SUMMARY Seven out of 12 normal subjects could deliberately produce abnormal pattern-reversal visual evoked potentials (VEPs) which simulated disorders of the anterior visual pathways without detection. In six the mechanism was near-point accommodation and in one eccentric fixation. If voluntary suppression of the VEPs is suspected various modifications to the recording technique may be of value. These include the use of a large check size and stimulus field and binocular stimulation.

The pattern-reversal visual evoked potential (VEP) is an important and sensitive technique for detecting disease in the visual pathways. The most useful index of abnormality is prolongation of the latency of the major positivity, P100, either absolute or relative to the opposite eye. Amplitude reduction is less reliable but an inter-ocular amplitude asymmetry of 50% is generally regarded as abnormal. The major clinical application of the VEP is in the diagnosis of multiple sclerosis but it is of considerable value in the investigation of visual failure. Whereas demyelinating optic nerve lesions typically cause P100 latency prolongation, compression of the anterior visual pathway is associated with waveform distortion and amplitude reduction, often with relatively minor latency increase. Stimulation of individual half-fields is helpful for localisation of chiasmal and post-chiasmal lesions and there are characteristic half-field waveform changes in optic nerve disorders which produce central or centro-caecal scotomata. Technical factors which influence the latency and amplitude of the VEP have been extensively studied and include the mean luminance, contrast, contour sharpness and pattern size.

The VEP may be useful in distinguishing between functional and organic visual loss. The amplitude of the P100 is particularly affected by reduced visual acuity and the combination of grossly reduced acuity and a well formed VEP of normal amplitude is a stronger pointer to hysterical visual loss whereas an abnormal VEP may be taken as evidence for organic cause. A recent study by Bumgartner and Epstein has demonstrated that normal subjects can deliberately alter or obliterate their VEPs; this has obvious implications for the use of the technique as an objective test in the assessment of visual failure. In this study the need for co-operation of the subject is reaffirmed and methods of voluntary alteration of the VEP are investigated.

Methods

Six male and six female healthy subjects participated in the study. Ages ranged from 21 to 40 years and all had normal corrected visual acuity. The stimulus was a black and white checkerboard pattern slide projected via a rotating mirror on to a translucent screen. The pattern field subtended an angle of 18° when placed 1 metre from the subject’s eye. Slides with three different check sizes were used: 34' (in routine use in the laboratory), 22' and 68'. The luminance of individual white squares was 1085 cd m⁻² and black squares 86 cd m⁻². Five channels of EEG were amplified and computer-averaged using a transverse occipital chain of Ag/Ag Cl recording electrodes placed so that the midline electrode was 5 cm above the inion with others 5 cm and 10 cm lateral to this. All were referred to a midfrontal electrode and the vertex was used for a ground. Pattern reversal occurred at 2 Hz and the EEG was sampled and averaged for 256 ms after the onset of each reversal. The time constant was 0-3 seconds (−3db) and the high frequency filter was at 300 Hz. A display oscilloscope allowed assessment of artefact and EMG activity. At least two runs of 128 reversals were averaged for each eye separately; the subject fixated on a red spot at the screen centre and the other eye was patched. Abnormality was defined as P100 latency more than 2:5 standard deviations (SD) above the mean, interocular latency difference of at least 9 ms or P100 amplitude less than 50% of the opposite eye.
Deliberate alteration of the visual evoked potential

VEPs were recorded first with a 34' check stimulus while fixing normally (perceiving). The subject was then asked to "make the pattern disappear without closing the eye or moving the eye about" and the VEP was again recorded (non-perceiving). More precise instructions on ways of non-perceiving the stimulus was not given. The procedure was repeated using 22' checks and 68' checks, perceiving and non-perceiving. Occular deviation and ptosis were carefully looked for and the subject immediately asked to correct. At the end of the test the subject was asked to describe the method used to make the pattern disappear. The eye patch was removed, the room fully illuminated and the subject demonstrated the manoeuvre while the positions of both eyes were noted.

In some subjects who were able to alter the VEP further experiments were performed during non-perceiving using a flash stimulus and using a 34' check pattern stimulus with binocular stimulation, half-field stimulation, the addition of lenses and prisms of various strengths and reduction of the eye to screen distance to 60 cm.

Results

Mean values for P100 latency and amplitude with the 12 subjects perceiving and non-perceiving the stimulus are given in table 1. All subjects had entirely normal VEPs according to a separate previously established control series when fixing and perceiving normally. Despite careful observation more than half of the subjects could voluntarily produce an abnormal VEP in one or both eyes when the standard 34' check was used (table 2). Amplitude reduction was accomplished more easily than delay in the VEP; two subjects could abolish the P100 and in seven there was a 50% fall in amplitude whereas four produced an absolute or relative abnormal latency prolongation (fig 1) without any detectable change in fixation. Seven subjects could increase the latency by 5 ms, some by as much as 20 ms, producing VEPs which might easily be regarded as evidence for optic nerve demyelination (fig 2). Small distorted VEPs typical of optic nerve compression were seen in others (fig 3).

Ability to alter the VEP was clearly affected by the size of the individual checks in the pattern stimulus (fig 4). More subjects could increase P100 latency with a small (22') check stimulus whereas the number of abnormal VEPs was reduced when 68' checks were used (table 2). Flash VEPs were virtually unchanged by deliberate non-perceiving of the stimulus.

Pupil size was monitored during all recordings; diameters ranged from 2–5 mm and never altered by more than 2 mm. Four subjects reported that they "made the pattern go away" by near point focusing, ie focusing on an imagined point in front of the screen. There was no detectable eye movement but slight pupillary constriction was noted. However, when the other eye was uncovered it was seen to be sharply adducted. All four had VEPs of abnormal latency with 22' checks, 3 with 34' checks and one with 68' checks. Two other subjects with abnormal VEPs could not describe the manoeuvre used but observation with both eyes uncovered indicated near point focusing. One subject produced a delayed small VEP by eccentric fixation on the top of the screen; this was not detected by the observers. One other produced a slight but not abnormal delay by fixing beyond the screen. The remaining four could not describe how they attempted to make the pattern disappear; no pupillary constriction or opposite eye adduction was seen and in these the VEP did not change.

VEPs with stimulation of individual right and left monocular half-fields were recorded in three subjects who could alter the whole-field VEP by near point focusing. The abnormal (ipsilateral) P100 was

seen in all the half-fields studied and none of the subjects showed a prominent contralateral P135 to account for the delayed major positivity on full field stimulation. Binocular VEPs were recorded in two of these subjects; they were unable to produce abnormal VEPs without detection of adduction by observers.

In two subjects VEPs were recorded during near point focusing while lenses of various dioptres were inserted. Both showed some improvement in the abnormal VEP with the addition of −3 dioptre lenses and dramatic improvement with −6 dioptre lenses (fig 5) but positive lenses did not normalise the VEP. The insertion of base-out prisms of up to +8 dioptre and base-in prisms of up to +24 dioptre had little effect on the abnormal P100.

Reduction in the distance between eye and screen made alteration of the VEP by near point focusing more difficult. Table 3 summarises the VEP data in three subjects with the screen at 1 metre and 60 cm from the eye, the angle subtended at the eye by each check being maintained at 34'.
Deliberate alteration of the visual evoked potential

Discussion

This study confirms the observation\(^\text{12}\) that normal subjects can deliberately alter the VEP to produce responses typical of disorders of the anterior visual pathway such as demyelination and compression without being easily detected.

Near point focusing was found to be the most successful method of altering the VEP. Near point focusing has three associated reflexes: pupillary constriction, convergence and near accommodation.\(^\text{13}\) This study suggests that the last of these three is particularly implicated in voluntary VEP alteration.

Reduction of pupil diameter from 8 mm to 2 mm reduces retinal illumination by more than 1 log unit, a change known to prolong P100 latency by more than 10 ms.\(^\text{67}\) However, in our subjects pupillary change did not exceed 2 mm and this alone was inadequate to account for the latency prolongation observed. Although there was marked adduction of the covered eye, movement of the tested eye was minimal, insufficient to shift the retinal image away from the macular area. This was confirmed by half-field studies which demonstrated a true delay of the macular-derived P100 component rather than enhancement of the paramacular P135. Further-
more the use of a base-out prism to shift the retinal image medially did not reverse the altered VEP during near point focusing, further evidence against convergence per se being the cause of the VEP change.

P100 latency can be prolonged and amplitude reduced by the use of defocusing lenses and this is particularly the case when stimulus check size is small.\textsuperscript{14,15} We found that voluntary suppression of the VEP was enhanced by the use of a small check and was made more difficult by decreasing the distance between eye and screen. In addition the abnormal VEP produced by near point focusing could be corrected by the addition of negative lenses. These facts suggest that near accommodation producing blurring of the pattern image on the retina is the principle mechanism involved.

Awareness of the possibility of deliberate alteration of the VEP is crucial for detecting a malingerer or hysteric. If the suspicion is raised that abnormal VEPs are factitious several modifications of the VEP technique may help to confirm this. Observation of the pupil may reveal miosis but this was not dramatic in our subjects and is by no means easy in a darkened recording room, especially in a subject with brown irises or wearing spectacles. Careful checking for ocular convergence is essential but it may be confused to the covered eye. Recording the VEP with binocular stimulation may be helpful; convergence may now be obvious or alternatively VEPs to binocular stimulation may be of considerably shorter latency and larger amplitude than when each eye is tested separately. Increasing the stimulus check size makes voluntary alteration more difficult but improvement in the VEP with increased check size does not per se confirm the suspicion of hysteria; we have noted that the delay in the P100 is more pronounced with small checks in some patients with subclinical optic neuritis. Sensitivity must be weighed with specificity; a robust stimulus such as flash or large check pattern is less susceptible to voluntary alteration or the effects of uncorrected refractive error but is also less sensitive in detecting optic nerve disease.

One subject used far accommodation to produce a small delay in the VEP. In laboratories where the stimulus screen is relatively close to the eye, for example 50 cm this method of voluntary alteration may be more important. Another subject altered the VEP by fixating on the upper edge of the screen, as has previously been reported by Uren et al.\textsuperscript{16} This suggests that though the use of a small stimulus field may improve the detection rate in optic neuritis\textsuperscript{17,18} it also makes ocular non-compliance by eccentric fixation more difficult to detect.

In conclusion normal subjects can deliberately produce abnormal VEPs by manoeuvres such as near point focusing and near accommodation which are not apparent to a careful observer. Techniques such as the use of large checks, a large stimulus field and binocular stimulation may be helpful in confirming this but it must be recognised that these techniques can reduce the accuracy of the VEP in detecting disease of the visual pathways.
