SUMMARY A study of 80 head injured patients revealed poor premorbid academic performance in up to 50% of the sample. Poor academic performance, as defined by diagnosis of learning disability, multiple failed academic subjects, or school dropout during secondary education, is not a previously cited risk factor for head injury. These findings have important implications in the identification of a high risk population and in the subsequent ability to reduce the incidence of head injury.

Head injury is the major cause of disability in the young adult. In 1974, 50 million Americans suffered accidental injury; head injury, sustained in 3 million, led to 70% of the subsequent deaths.1 Traumatic head injury presents a major health problem; in the United States in 1974, 422,000 new cases occurred, a rate of 200 head injuries/100,000 population per year.2

The costs relative to head injury are staggering. American figures published in 1980 estimate 3.9 billion dollars per year.2 Medical expenses account for one-third; social costs, such as disability payments and lost income, comprise two-thirds. It is likely that these costs are underestimated. Dollar figures do not encompass the cost of suffering in human terms.

To date, no treatment after severe head injury is totally restorative; in this context, avoidance of such injury becomes critical. Efficient preventive efforts require knowledge of risk factors. It is known that 63% of victims are younger than 25 years of age and males outnumber females by more than two to one. Over half of the injuries result from motor vehicle accidents and more than 60% of the drivers have elevated blood alcohol levels. Thus, persons most at risk for head injury are adolescent and young adult males operating a motor vehicle while intoxicated.3

Several authors imply that head injury occurs primarily in persons who functioned suboptimally premorbidly. Fahy et al4 found that 46% of their patients had been “maladjusted in some way”. Fuld and Fisher5 noted that only three of 18 head injured children had been normal academically and socially before the accident. Fell,6 investigating fatal motor vehicle accidents in four US cities, reported elevated blood alcohol levels in offenders. The typical offender was a 20–35 year old single or divorced male, with a 12th grade education at best, and often with a history of driving violations, including a suspended licence.

Minimal brain dysfunction and hyperactivity

There are several studies, such as that of Laufer and Denhoff7 in 1957, which have concluded that hyperactivity disappears by early adulthood. However, it is more recently generally acknowledged that persons with one of a number of diagnoses in childhood, including minimal brain dysfunction and hyperactivity, may continue to encounter problems as adults. Other studies demonstrate that children with minimal brain dysfunction and hyperactivity may continue to be impulsive and distractible as adults, and may develop psychosis, alcoholism, addiction, sociopathy and personality deficits.8–12

Learning disability

There are fewer studies concerning the developmental outcome of children with learning disability. Ackerman et al13 and Wender14 reported that some authors believe that difficulties are outgrown during the maturational process. Conversely, Cox15 stated that lack of self-confidence and below average career success are common, and Culbertson and Ferry16 described persistence of learning problems into adult life. Weiner17 postulated that poor peer relationships result from deficiencies in interpersonal cognitive problem-solving skills. Kronick,18 too, cited that
interactional inadequacies of learning disability children become paramount after they leave school. Deficits are noted in social perceptiveness, judgement, concentration, capacity for intimacy, and strength of self-concept. Such persons profit poorly from previous experiences, and may be unsuccessful in vocational, marital, and parenting roles.

Other authors, discussing problems encountered in adolescence, make particular reference to the high percentage of juvenile delinquents who, upon investigation, have learning disability.19–21 Mauser22 described eight similarities between learning disability and juvenile delinquency, although Spreen23 disputed this connection in a 4–12 year follow-up of 203 learning disability children.

The prevalence of learning disability is quoted as anywhere from 1% to 20% of school-aged children.24 Most estimates are between 2% and 4% in the United States.16

Academic failure
Information concerning the outcome of the majority of students with academic failure, who have not been specifically diagnosed as having attention deficit disorder, minimal brain dysfunction, hyperactivity, or learning disability, is elusive.25 Most articles about underachievers and dropouts discuss aetiology, treatment, and prevention, rather than long-term outcome.26 Beck and Muia27 do, however, allude to interpersonal alienation and inability to hold a job as part of the dropout syndrome.

The national dropout rate from high school is estimated at anywhere between 11% and 28%, with an overall figure of 23%.28 The dropout rate for California is estimated at between 16-8% and 30%.28 29 The higher rates apply, in general, for inner city, ghetto, or minority student populations.

During the course of a formal, prospective study of 80 traumatically head injured patients,30 a surprising number were noted to have been poor students premorbidly. This observation suggested the hypothesis that poor academic performance is an additional, previously unreported indicator of an increased risk of head injury.

Methods
The subjects of this investigation were 80 patients sequentially admitted to the Santa Clara Valley Medical Center (SCVMC) in San Jose, California. All had suffered severe blunt traumatic head injury from one to 18 months prior to admission. They met the following criteria: (1) admission as inpatient to the SCVMC acute head injury rehabilitation unit; (2) comatose for longer than 6 hours; and (3) between 15 and 60 years of age. Demographic characteristics of the 80 patients were similar to those reported in other head injury studies. Sixty-one per cent of the patients were 25 years of age or younger, the male to female ratio was 2:5:1, and motor vehicle accident was the aetiology of injury in 69% of the cases. Ethnic minorities comprised 20% of the 80 patients.

Parameters selected to indicate poor scholastic achievement were: (1) multiple (two or more) failed academic subjects in one semester; (2) school dropout; or (3) premorbid diagnosis of learning disability. Information was obtained from school records, reports of premorbid examinations by paediatricians and school psychologists, and interviews with the patients’ parents during and after hospitalisation.

The medical records of all 80 patients were reviewed. Subsequently patients were divided into two groups: those born prior to 1952, educated before learning disability was widely recognised within the educational system, and those born during or after 1952, educated after public laws mandating identification of learning disability had generally been enacted.

Results
Of the 80 patients, 27 (33.7%) were reported as having demonstrated poor academic achievement or had been designated learning disabled. Exclusion of the 16 patients for whom information about school performance was not available reduced the number to 64 patients. The 27 underachievers represent 42.2% of this group (tables 1 and 2).

Twenty-eight of the total group of 80 patients were born prior to 1952. Of this group, four, or 14.3% failed in school. Exclusion of 10 patients of the 28, those for whom records are incomplete, reduces the total to 18, of whom the four underachievers comprise 22.2%.

Fifty-two patients were born during or after 1952. Of this group, 23 or 44.2% had poor premorbid academic histories. Exclusion of the six patients with incomplete records reduces the total to 46; of this group, the 23 poor achievers represent 50%. (The higher prevalence of poor achievers born after 1951 may reflect the impact of public legislation which promoted identification of those with learning disability or a reduction in relative risk with age.)

In the group of 23 poor achievers born during or after 1952, the male:female ratio was 3:1. Aetiology of head injury was motor vehicle accident in 61%, pedestrian versus motor vehicle in 22%, and altercation in 9%.

Discussion
Our results indicate that 50% of severely head-injured patients who were educated after learning disability was well known, demonstrated poor premorbid academic performance. This association suggests that persons who have done poorly in school have a definite increased risk of sustaining head injury. We
do not define impaired scholastic performance as a specific syndrome; rather, it is a constellation of symptoms which includes multiple failing grades, school dropout, or learning disability.

Multiple failing grades are readily documented. Dropouts are students who leave school and do not return within that educational year. Such failure may reflect a student's difficulties with language or academic skills, lack of guidance, a poor social environment, behavioural difficulties, boredom, or limited flexibility of educational programs.

The concept of learning disability developed in the US in the 1950s and 1960s, with passage of legislation assuring its widespread recognition by 1970. It usually describes children of at least average intelligence who demonstrate impaired perception, cognition, gross or fine motor skill, or language development, and who function from one to several years behind grade level in at least one academic subject. With time, the boundaries of this syndrome have blurred into those of minimal brain dysfunction, hyperactivity, and attention deficit disorder. In other countries there is less tendency to categorise behavioural and educational dysfunction. In fact, a British paediatric neurologist has written that minimal brain damage is not a diagnosis; it is an escape from making one.

Although the systems and language of evaluation vary between countries, a universal fact is that some students suffer academic failure. While congruence of terms between educational systems would be ideal, this is not essential to recognise students who are at risk.

Our results reveal that a higher percentage of head-injured patients had a history of poor academic performance than would be expected based upon even the most generous estimates of dropout prevalence (50% in the study after 1951, as contrasted to a dropout rate of between 17 and 30% state-wide). The statewide rate cannot be compared directly to the prevalence of poor academic history in our sample because the state maximum figure of 30% includes only dropouts, rather than those with learning disability or failed classes. Nevertheless, it appears that the sample does have a significantly higher prevalence of premorbid problems than the general public.

Several explanations may account for this high prevalence. Perhaps the apparent increased risk of head injury results from continued expression of the primary symptomatology of these children. Distraction, poor attention span, or inability to focus upon relevant factors may predispose to accidents. Limited frustration tolerance, impulsivity, or poor judgement may do likewise. Deficiency in ability to anticipate situations accurately and to plan appropriately may render persons vulnerable to accidents. Perceptual-motor deficits, figure-ground confusion, difficulty with spatial relationships, and cognitive impairment persisting into adulthood may compromise one's ability to process incoming information correctly, or to respond in a precise, calculated manner.

Alternatively, head injury may result from developments which occur as secondary processes. Children who fail in school may grow up socially stigmatised, with feelings of rejection, inferiority and isolation. They may become rebellious, egocentric, and sociopathic, and less able to cope well with the increasing responsibilities of adolescence and adulthood. Substance abuse may occur and predispose to accidental

Premorbid prevalence of poor academic performance in severe head injury. Even the experience of previous single or multiple head injury may not provide protection against re-injury.

The findings of this study may have significant implications for formulation of rehabilitation goals and treatment plan. Both the rate and degree of the recovery process may be affected by premorbid limitations in academic performance.

These findings may also have significant implications for public health policy. Prevention of head injury is far more efficacious than any treatment currently available; therefore, the additional risk factor we have described should be addressed by preventive programmes. It is known that children who demonstrate poor academic achievement should be screened medically, provided special education classes for academic remediation, and taught basic socialisation skills. Counselling about alcohol, drugs, and vocational options is important. Our results indicate that safety awareness and intensive driver education with refresher courses may also be warranted. Drivers' licences could be granted later than the customary age of 16 to 18 years. In this identified population, driving violations, which indicate potential for future catastrophe, require serious attention. We believe that the findings of this study identify a previously unrecognised subpopulation at increased risk for significant head injury and for whom specific, preventive interventions may be indicated.
