Use of the polymerase chain reaction to detect herpes simplex virus DNA in paraffin sections of human brain at necropsy

J A R Nicoll, N J Maitland, S Love

Abstract

The feasibility of detecting herpesvirus DNA in paraffin sections of routinely fixed and processed human necropsy brains by use of the polymerase chain reaction (PCR) was assessed. A 110 bp segment of the thymidine kinase gene of herpes simplex virus type 1 (HSV1) could readily be amplified in sections from the brains of six patients with acute HSV1 encephalitis but not from those of six patients with other neurological diseases, including varicella-zoster encephalitis and herpes simplex virus type 2 encephalitis. Primers suitable for amplifying c-myc were included in the PCRs for assessment of DNA preservation. This was found to be adequate to allow amplification of c-myc DNA in sections from all of the brains studied. The PCR provides a simple and specific means of detecting HSV1 DNA in routinely processed necropsy material.

The detection of herpes simplex virus in the central nervous system by conventional histological methods, including immunohistochemistry and electron microscopy, is not usually possible after the first three weeks of the illness, although data obtained by Southern blot analysis of brains from experimentally infected animals suggests that viral DNA may be detectable for much longer. Recent demonstration of successful primer-directed amplification of DNA from paraffin sections of biopsy material promoted us to assess the feasibility of detecting herpes simplex virus DNA in paraffin sections of human necropsy brains by use of the polymerase chain reaction (PCR).

Methods

Blocks of formalin-fixed, paraffin-embedded necropsy brain tissue that had been stored for periods ranging from one to 20 years were used. Sections 10 µm in thickness were cut from temporal or frontal lobe blocks from six patients with acute herpes simplex virus type 1 (HSV1) encephalitis and six controls (table). The controls included a case of herpes simplex virus type 2 (HSV2) encephalitis and a case of varicella-zoster encephalitis, confirmed serologically. The duration of symptoms in the HSV1 encephalitis patients had ranged from five to 21 days. Two of these patients had significant rises in the level of serum antibodies to HSV1. The diagnosis of herpes encephalitis had been confirmed in all cases by immunohistochemistry of necropsy brain sections and, in some cases, also by culture and electron microscopy.

The following pairs of oligonucleotide primers, suitable for amplifying a 110 bp fragment of the thymidine kinase gene of HSV1, and a 75 bp fragment of c-myc were synthesised in the Department of Biochemistry, University of Bristol: thymidine kinase primers 5'-ATACCGAGATATGGCACC-3' and 5'-TTATTTGGCCTCAGGGCGG-3', c-myc primers 5'-GGAGGCTATTCTGCCACCGCTT-3' and 5'-TGCAAGGAGAGCCTTTACCA-3'. The PCR technique was similar to that described by Shibata et al. The sections were collected in 700 µl Eppendorf tubes,
dewaxed by vortexing for one minute in 400 µl of xylene and pelleted by centrifugation. The supernatant was discarded and the residual xylene removed by vortexing in two 400 µl changes of absolute alcohol. After vacuum desiccation, the samples were resuspended in 50 µl of water and heated to 95°C for 10 minutes. PCR buffer (50 µl) was then added to give final concentrations of 0-02-0-1 µM primers, 200 µM dNTPs, 50 mM KCl, 1-5 mM MgCl₂ and 5 units of Taq polymerase in 10 mM Tris-HCl, pH 8-3. The mixture was subjected to 30 thermal cycles, each consisting of denaturation for two minutes at 94°C, annealing of primers for two minutes at 55°C, and primer extension for three minutes at 72°C. Amplified DNA was separated by 10% polyacrylamide gel electrophoresis, stained with ethidium bromide and visualised by UV-induced fluorescence.

Results
Detection of viral DNA
In all six cases of acute HSV1 encephalitis examined, including two that had been given acyclovir treatment, DNA fragments of the predicted 110 kb size were amplified with the thymidine kinase primers (fig). None of the control sections contained detectable HSV1 DNA.

Detection of c-myc
In all of the sections examined, from both HSV1 encephalitis and control brains, the 75 bp fragment of genomic c-myc DNA was readily amplified (fig). The c-myc amplification seemed to be enhanced in those cases in which there was also amplification of the 110 bp fragment of the HSV1 thymidine kinase gene (lanes 1-6 in fig). The reason for this is not clear. When the thymidine kinase primers were left out of the reactions the intensity of the c-myc bands was similar in the HSV1 cases and controls.

Discussion
Present findings show the PCR to be a simple and specific method for the detection of HSV1 DNA in paraffin sections. Rowley et al recently reported the use of primer-directed amplification to detect HSV1 DNA in the cerebrospinal fluid of four patients with herpes simplex encephalitis and, as in this study, no false positive or negative results were obtained. The maximum documented duration of illness in their patients was only seven days. Further studies should provide more information as to the duration of detectable infection, the effects of antiviral treatment, and the possible establishment of latent HSV infection within the central nervous system.

Rogers et al reported that fixation for one week in formalin caused appreciable degradation of the DNA templates with a decline in the efficiency of PCR amplification. However, all the brains examined in this study had been fixed whole for at least three weeks in 10% unbuffered formalin, processed to paraffin wax over a six day period, and stored for up to twenty years. Blocks of paraffin-embedded tissue are a ready source of a wide range of pathological material suitable for studies of viral and cellular DNA by use of the PCR. Our results indicate that the technique can be applied not only to biopsy material, which is fixed for a relatively short time and then processed to paraffin wax over a period typically less than 24 hours, but also to necropsy specimens fixed for several weeks in formalin and subjected to much longer processing schedules.

We thank Dr Margaret Easri for providing material from the case of HSV2 encephalitis. This work was supported by the Wellcome Trust.
