Traumatic basal ganglia haemorrhage with slight clinical signs and complete recovery

A traumatic basal ganglia haemorrhage is a rare but serious complication of head injury. Recognition of its prevalence and clinical features has been made possible by the advent of CT. We describe a patient with a large traumatic basal ganglia haemorrhage with slight neurological signs and complete recovery. A 15 year old right handed young woman sustained a left frontotemporal injury in a motorcycle accident. Witnesses reported a short loss of consciousness (lasting a few seconds) accompanied by a sudden and brief extensor "stiffening" of all limbs and followed by a confused state (lasting a few minutes). On admission to the emergency department an hour later she was awake and fully orientated and reported retrosteroide amnesia of a few minutes' duration. General physical and neurological examination were normal, as were X ray pictures of skull, chest, and cervical spine, routine laboratory investigations and EEG. The next day she was still alert and cooperative, but complained of diffuse, moderate to severe, band-like headache. She had a very slight weakness of her left lower facial muscles. Her EEG showed a drowsy pattern (flattening with bilateral central and occipital slow waves, with inverted arousal reaction) without out clear cut abnormalities. Two days later a repeat EEG showed right temporoparietal focus, with predominant high voltage waves, spreading medially to the ipsilateral hemisphere. A brain CT scan showed a medium sized haemorrhage surrounded by a slight oedema in the anterior half of the right lentiform nucleus, with a slight depression of the frontal horn of the lateral ventricle and displacement of the anterior limb and genu of the internal capsule and the head of caudate nucleus (figure). Over the following days the facial weakness disappeared completely. A repeat CT ten days later showed a reabsorption of the haemorrhage. The EEG had reverted to normal. A right carotid angiogram did not show a vascular lesion.

Traumatic basal ganglia haematomata is a rare (3%) complication of severe closed head injury, occurring mainly in the young, the proposed underlying mechanism is shearing of an anterior choroidal or lentioistriate artery due to violent acceleration-deceleration brought about by a high velocity injury. In almost every case the haemorrhage is accompanied by the usual pathological features of severe head injury—for example, diffuse axonal injury, multiple contusions, and epidural or subdural haematomata. In one large series patients with a traumatic basal ganglia haematomata had a poor prognosis but cases with a favourable outcome have been reported. Basal ganglia vascular lesions that do not involve the internal capsule may be asymptomatic, and subcortical vascular lesions of the dominant hemisphere may bring about only aphasic disturbances or even be clinically silent. Small basal ganglia haemorrhages in the non-dominant hemisphere may not be associated with the typical cognitive and behavioural disturbances (left neglect, visuospatial impairment etc.). The interest of the present case lies in its favourable outcome. Although an early CT examination was not performed, we suggest that the early absence of neurological and EEG abnormalities reflected a slow development of the haematoama.

Transient pure sensory strokes in patient with aneurysm of rostral basal artery

Pure sensory stroke (PSS) usually results from a lacunar infarct in the sensory nucleus of the thalamus; however, ischaemic and haemorrhagic lesions with various locations have also been reported. We studied a patient with PSS in whom an aneurysm of the rostral basal artery was disclosed by CT scan and MRI.

On the day of admission a 78 year old, right handed man suddenly developed three brief episodes of numbness and unpleasant dysesthesia on the right side of the body. He had no headache, stiff neck, dizziness, or visual symptoms. He was in good general health, with no history of arterial hypertension, which was well controlled with medication. Neurological examination performed during one of the episodes showed that he was conscious, well oriented, and aware of his disorder. There was loss of temperature and pain sensation affecting the left side of the body including the face. Touch, vibration, position sensitivity, graphesthesia, and stereognosis were normal, and no other neurological deficits were seen. A few minutes later the symptoms resolved spontaneously, and the neurological examination showed no objective sensory disturbances. Speech and language and other neurological examination were normal.

General physical examination was unremarkable and laboratory studies showed normal results. Electroencephalogram, somatosensory, brainstem auditory, and visual evoked potentials were also normal. The CT scan showed a round area of contrast enhanced density in the region of the interpeduncular fossa, with the CT features of a rostral basal ganglia aneurysm (figure, top). MRI confirmed the presence of an aneurysm extending from the upper pons to the inferior aspect of the third ventricle without affecting the thalamus and compressing the left cerebral peduncle slightly (figure, middle). MRI disclosed hypointense images within the aneurysm, suggesting a clot inside its lumen (figure, bottom). Both CT scan and MRI did not show any abnormality of a focal nature in the brainstem, internal capsule, basal ganglia, or cerebral hemispheres. A digital venous angiogram showed no stenosis or ulceration in the carotid or basilar arteries. Reassuringly, on the subsequent day a normal neurological examination, and the patient reported that no other similar disturbances had occurred.

The neurological disorder in this patient met the established criteria for transient ischaemic neurological deficit (TIA) as they resolved within a few minutes after onset. Both CT scan and MRI showed a sacculated aneurysm of the rostral basal arteries six months after any other pathological change elsewhere in the brain. Therefore the precise vascular territory affected cannot be identified, but on the basis of the aneurysmal location the erent vascular supply of the thalamus or of the upper midbrain explains the symptoms and signs presented. Asymptomatic aneurysms

Figure CT scan showing right basal ganglia haemorrhage

sensory disturbances closely resembling an ischaemic process.

Intra-arterial embolism of an aneurysmal sac thrombosis is considered a possible cause of transient ischaemic deficit or collapsed stroke in patients with unruptured, intracranial aneurysms. In our case the demonstration by MRI of intraluminal thrombosis material inside the aneurysm gives support to the view that thrombi may have dislodged from the clot and embolised into the distal vessels. Alternatively the thrombosis process may extend from the aneurysm and involve the lumen of an artery arising from the basilar artery and so cause ischaemia. On the other hand, it seems unlikely that platelet embolisation from an extracranial source was the cause because the patient had no stenosis or ulceration in these vessels; neither a cardiac source, systemic hypotension, nor underlying conditions predisposing to hypercoagulability were identified.

Regardless of the physiopathological mechanisms, the case reported shows that the PSS syndrome can occur secondarily to a basilar aneurysm and provides another example of the many potential aetiologies of lacunar syndromes.

Ectopic parapallidal putitary adenoma with subarachnoid seeding

There are very few descriptions of an ectopic supra- or parapallidal putitary adenoma in a patient with a normal intrasellar putitary gland. In one case the tumour originated in the parasellar region, and in a third case the tumour arose either in the sphenoid or in the pars tuberalis.

We report a further case of ectopic parapallidal putitary adenoma which was complicated by subarachnoid seeding 13 years after initial treatment by craniotomy, radiotherapy and systemic chemotherapy.

In 1975 a 45 year old man who had been impotent for 20 years was found to have a left sided oculomotor paresis. Radiographs showed a normal pituitary fossa and para nasal sinuses. Orbital venography, otoiod angiography and basal cisternography suggested a left parapallidal lesion. The patient's hormonal iodine concentration was low (0.23 mmol/L; normal range 0.24-0.48), his serum prolactin concentration was not determined. Cranial CT disclosed two mucoid tumours. One was pea-sized, seemed to infiltrate into the left oculomotor nerve near its entrance into the cavernous sinus, and was removed incompletely. The other tumour was bean-sized and located under the left optic nerve; this tumour was removed completely. The pathologists who were consulted had difficulty in making a definite diagnosis: reticulosaurocma and malignant epithelial tumour were suggested. An extensive search for a primary tumour was not performed. The patient was treated with radiotherapy followed by systemic chemotherapy (12 courses of cyclophosphamide and vincristin). The patient's whole brain irradiation treatment down to (para)sellar areas was given up to 60 Gy. Special attention was paid to include the suprasellar area for up to 3 cm, and the whole of the sphenoid; the clivus was only partly irradiated. In 1979 a CT of the brain revealed nothing abnormal.

In 1988, the patient was found in an unkempt condition and was admitted in a delirious state and with neck rigidity. Body temperature was 34.7°C. T4, FTA index and T3 uptake were 65 nmol/l (N = 80-150), 55 nmol/l (N = 70-170) and 0.66 nmol/l (N = 0.95-2.20) respectively. Serum TSH was normal. CFT protein was 20 gr/l, cell count was normal and no abnormal concentration of the fluid did not identify tumour cells.

The patient's condition improved with general supportive treatment and levothroxyrin and dexamethasone. CT and MRI of the brain and spinal cord identified a mass located anterolateral to the pons and medulla oblongata, mainly on the right side and extending down to the sixth cervical vertebra.

Intrasellar lesions were also present in the high and mid thoracic regions. To obtain a tissue diagnosis, stereotactic biopsies were taken under local anaesthesia. Smears made during this procedure suggested a putitary adenoma. The patient died suddenly on the third postoperative day. At necropsy the immediate cause of death appeared to be asphyxiation of food. No other abnormalities were found outside the central nervous system. Grossly as well as microscopically no abnormalities were found in the para- and suprasellar region, putitary fossa or sphenoid sinuses.

Aoid tumour tissue was found in the lesions shown by CT and MRI. Histopathologically, the tumour consisted of sheets of medium-sized epithelial cells with round or ovoid nuclei surrounded by faintly stained amorphous cytoplasm. Mitotic figures were rare and nuclear polymorphism was inconspicuous. Immunoreactions for keratin and NSE were positive, and for S-100 weakly positive. Very few cells reacted positively for chromogranin A. Between 10-25% of the cells reacted strongly for prolactin, less than 10% for growth hormone. Ultrastructural examination of stereotactic biopsy showed a few 100-200 nm dense granules, often surrounded by a membrane (figure). The histological appearance of the specimens obtained from 1975 and 1988 were identical; the paraffin blocks from 1975 were not available for further study. The diagnosis therefore was of an ectopic parapallidal putitary adenoma, with a normal intrasellar putitary producing leptomeningeal seeding. The persistence of occult tumours in other supra- or parapallidal putitary adenoma with a normal intrasellar putitary gland is not surprising in view of the recognition by Hori of "para" adenohypophyseal cells in the leptomeninges surrounding the pituitary stalk and infundibulum. These cells were found in all foetuses examined and in 75% of adult necropsies. In the present case, between
