The effect of immunosuppression on the development of cerebral oedema in an experimental model of intracerebral haemorrhage: whole body and regional irradiation

P J Kane, P Modha, R D Strachan, S Cook, I R Chambers, C B Clayton, A D Mendelow

Abstract
The oedema which forms around an intracerebral haemorrhage has a complex aetiology. The immune response may have a role in its formation. There is clinical and experimental evidence that circulating leucocytes and platelets may mediate oedema formation. Global depletion of circulating leucocytes and platelets by whole body irradiation in a rodent model of intracerebral haemorrhage was found to confer protection against both ischaemia and oedema formation. This was not a direct effect of irradiation of the brain. The possible mechanisms for this protection are discussed.

(J Neurol Neurosurg Psychiatry 1992;55:781–786)

Spontaneous intracerebral haemorrhage is a significant cause of mortality and morbidity. Brain oedema secondary to the haemorrhage is a major clinical problem which often proves refractory to treatment. In experimental models the brain oedema that develops after intracerebral haemorrhage is, in part, due to ischaemia. Brain oedema has also been shown to follow the inflation of a 50 μl balloon in a model which simulates the mechanical component of a rapidly expanding mass in the rat caudate nucleus.

Attention has recently focused on the role of the cellular constituents of blood in generating cerebral oedema. This can be considered from two points of view: firstly, the direct effect of the cellular constituents within the haematoma, and secondly, the influence of circulating red cells, leucocytes, and platelets on the development of ischaemic oedema. With the first consideration in mind, Jenkins et al have shown that stereotactic injection of autologous blood into the basal ganglia of rats produces greater ischaemia than an equal volume of inert oil of cerebrospinal fluid. Suzuki and Ebina, in a similar experiment on dogs, have shown that the volume of oedematous brain is greater after injection of blood than after injection of an inert oil. Both ischaemia and oedema are therefore not merely a result of the mass effect of the haematoma but are dependent on other factors inherent within the blood inside the haematoma.

With regard to the second mechanism, neutrophils and platelets have been shown to accumulate rapidly in ischaemic brain both experimentally and in human stroke. Circulating neutrophils have a role in producing ischaemic damage in heart, bowel, and lung and have been implicated in the generation of ischaemic brain damage. Similarly, platelets have the potential to cause ischaemic brain damage. The aim of this study was to determine whether depletion of circulating leucocytes and platelets influences the production of cerebral oedema in a rat model of intracerebral haemorrhage.

Methods
Adult male Wistar rats (280–370 g) were used for the study. All experiments were performed in accordance with the Animals (Scientific Procedures) Act 1986.

Intracerebral haemorrhage was simulated by inflation of a microballoon placed stereotactically in the right caudate nucleus, as previously described by Kingman et al. This model has been extensively investigated and proved to produce brain oedema.

Leucocyte and platelet depletion were achieved by bone marrow suppression using sublethal irradiation with x rays. The specification of x ray quality was 240 kV constant potential and 3-5 mm Cu half value thickness. The rat, including tail, was restrained in a perspex tube. The tube design prevented the rat from moving during the period of irradiation without compromising ventilation and without the need for anaesthesia. An x ray dose of 5 Gy was given over 15 minutes, either as a whole body dose or, by appropriate lead shielding, to the head alone or the body and tail alone. Uniformity of dose distribution throughout the irradiated volume within a range of 5% was achieved by treating the immobilised animal equally through each flank. Control animals were restrained in the tube for an equivalent period but were not irradiated. Experiments were performed in three groups.

Group 1: Whole body irradiation, 4 hour oedema measurement
Surgery took place four days after whole body irradiation (treated n = 7, control n = 5). Anaesthesia was induced in an atmosphere of 3–5% halothane in nitrous oxide-oxygen (70%: 30%) and maintained by face mask (halothane reduced to 1–2%) while a tra-
Cheostomy was performed and mechanical ventilation initiated. Thereafter anaesthesia was maintained using 0.5–1% halothane. Expiratory carbon dioxide was continuously monitored by using a capnograph and recorded on a polygraph. Body temperature was maintained at 37°C by using a homeothermic heating unit. The right femoral artery was cannulated to allow serial measurement of blood gas tensions, glucose concentration, packed cell volume, and pre lesion full blood count and differential white cell count. Pulsatile and mean arterial blood pressure were continuously monitored and recorded on a polygraph. The left femoral vein was cannulated to allow fluid replacement at 2–3 ml per hour. The rat was then placed in a stereotaxic frame and a midline sagittal scalp incision made. After reflecting the pericranium burre holes were made to allow insertion of the microballoon (right side, 2.8 mm lateral and 1.1 mm anterior to the bregma) and bilateral frontal and parietal platinum cortical electrodes (2.8 mm lateral and 3 mm anterior/posterior to the bregma) for cerebral blood flow measurements using a hydrogen clearance technique. The electrode diameter was 125 μm and the electrodes were placed a depth of 1 mm into the cortex. The position of the right sided electrodes was designed such that they would lie in the ischaemic penumbra of the simulated intracerebral haemorrhage. Baseline cerebral blood flow measurements were taken at this point. A microballoon (Ingmar Laboratories) mounted on the tip of a blunted 25 g butterfly needle was inflated to 50 μl with saline to test its integrity. It was then deflated and inserted to a depth of 5.5 mm into the right caudate nucleus and then re-inflated to 50 μl with saline. It remained inflated for the duration of the experiment. Cerebral blood flow measurements were taken at five and 30 minutes after inflation and thereafter each 30 minutes. At 240 minutes the animal was killed with intravenous pentobarbitone and the brain rapidly removed for oedema measurements.

**Group 2: Whole body irradiation, 72 hour oedema measurement**

Surgery took place four days after whole body irradiation (treated n = 8, control n = 7). Before surgery venesection for full blood count and differential white cell count was performed. Anaesthesia was induced by intraperitoneal injection of a mixture of midazolam (1.25 mg/ml), fentanyl (0.08 μg/ml), and flunisone (0.25 mg/ml) at a dose of 1 ml/300 g body weight. This method of anaesthesia maintains normal blood pressure and arterial blood gas tensions in spontaneously breathing rats. A microballoon was inserted as for group 1. It was inflated to 50 μl with saline for five minutes, deflated, and removed. In a previous study this period of balloon inflation followed by reperfusion of the adjacent brain produced significant oedema. After ensuring haemostasis the burre hole was sealed with bone wax, sprayed with topical antibiotic, and the wound sutured. The rat was transferred to an oxygenated incubator for recovery. In the early postoperative period it received buprenorphine analgesia and 5 ml of dextrose/saline subcutaneously as fluid replacement because rats frequently take no oral fluids in the 24 hours postoperatively. At 72 hours the rat was anesthetised in an atmosphere of 5% halothane and killed with an intracardiac injection of pentobarbitone; the brain was rapidly removed for oedema measurements.

**Group 3: Differential irradiation, 72 hour oedema measurement**

Surgery took place seven days after irradiation. This increase in time between irradiation and surgery leads to greater depletion of leucocytes and platelets at the time of balloon inflation. Treatment groups were: whole body irradiation (n = 10); head only irradiation (n = 10); body only irradiation (n = 9); control (n = 24). The animals were treated as for group 2.

**Assessment of brain oedema**

Coronal slices of both hemispheres, 1 mm thick, were taken either side of the point of entry of the microballoon on the right cortical surface. Two 1–2 mm² samples of tissue were taken from the cortex overlying the haematoma, from the white matter adjacent to the haematoma, and from the caudate nucleus in the penumbra of the haematoma. Equivalent samples were taken from the left hemisphere and also paired control samples from both cerebellar hemispheres. Brain oedema measurements were made using the gravimetric technique described by Nelson et al but modified according to Shigeno et al.

The samples were dropped into the gravimetric column and their level of descent measured after one minute. The specific gravity of the sample was calculated using a linear regression analysis derived from calibration of the column with droplets of potassium sulfate of known specific gravity. All columns had a correlation coefficient greater than 0.999.

The investigators remained blind to the treatment groups until all experiments were completed. Statistical analysis of the group 1 and group 2 experiments was carried out using an unpaired Students t test. Analysis of the group 3 results was performed using a one way analysis of variance (ANOVA). When this analysis confirmed the presence of significant differences between the treatment groups, these were further evaluated with an unpaired Students t test using the pooled variance derived from the ANOVA.

**Results**

**Group 1: Whole body irradiation, 4 hour oedema measurement**

**Physiological variables**

There were no significant differences detected in pH, the carbon dioxide and oxygen pressures, and mean arterial blood pressure between control and irradiated animals (table 1).

HAEMATOLOGICAL INDICES
Platelet and white blood cell count were significantly reduced in the irradiated animals when compared with the control group (table 2).

CEREBRAL BLOOD FLOW
In the non-irradiated control animals there was a significant reduction in blood flow in the right frontal region at 60, 90, 120, 150, and 180 minutes when compared with baseline values (fig 1). In the irradiated group a significant reduction in flow was observed only at 210 minutes (fig 1). Right parietal blood flow was significantly reduced at 210 minutes in the control group but not in the irradiated group. No significant blood flow changes were found in the left (unoperated) hemisphere in either group.

BRAIN ODEMA MEASUREMENT
All animals developed significant oedema in the right hemisphere in tissues around the simulated intracerebral haemorrhage. There was significantly less oedema formation in the right caudate nucleus of irradiated animals when compared with controls (fig 2). No significant changes were detected in the other areas investigated.

Group 2: Whole body irradiation, 72 hour oedema measurement

HAEMATOLOGICAL INDICES
Platelet and white blood cell count were significantly reduced in the irradiated animals when compared with the control group (table 2).

BRAIN ODEMA MEASUREMENT
All animals developed significant oedema in the right hemisphere in tissues around the
simulated intracerebral haemorrhage. There was significantly less oedema formation in the right caudate nucleus of the irradiated animals when compared with non-irradiated controls (fig 3). No significant changes were detected in other areas investigated, though there was a trend towards less oedema formation in the cortex and white matter in the irradiated group.

**Group 3: Differential irradiation, 72 hour oedema measurement**

**Haematological indices**

Changes in the leucocyte, platelet, and differential white cell counts with time in each of the treatment groups are shown in table 3. The animals treated with whole body or body only irradiation showed a significant reduction in the circulating leucocyte and platelet counts when compared with the controls. In both groups the neutrophil and lymphocyte counts were both reduced, with the lymphocytes showing a greater percentage change from pretreatment values. The reduction in leucocyte and platelet counts was quantitatively greater with whole body irradiation than with body only irradiation, although this did not achieve significance. The trend to higher values for each cell type in the body only irradiated group presumably reflects the haemopoietic activity of the skull marrow. In the head only irradiated group the leucocyte count was significantly increased when compared with control values whereas platelet count was not significantly different. This increase in leucocyte count was made up wholly by an increase in circulating neutrophils.

**Brain oedema measurement (fig 4)**

All animals developed significant oedema in the right hemisphere in tissues around the simulated intracerebral haemorrhage. Head only irradiation produced significantly greater oedema in both cortex and caudate nucleus when compared with control values. Whole body irradiation resulted in significantly less oedema in the caudate. Although a trend in this direction was also observed in the cortex, this was not significant. Body only irradiation did not confer any protective or detrimental effect in cortex, caudate, or white matter. Cerebellar specific gravity was significantly lower in this group. This might be explained by the difficulty in cutting the cerebellum to produce pure cortical samples for microgravimetry. Therefore whole body irradiation seems to confer some protection against the development of oedema that is independent of a local effect of the irradiation on the brain.

**Discussion**

The oedema that surrounds an intracerebral haemorrhage is a complex phenomenon. Its production is dependent on the interaction of a wide variety of local factors.

The mechanical disruption and compression of brain tissue by an expanding haematoma produces a penumbra of ischaemic and oedematous brain. Experiments in animal models have shown that the volume of oedema and ischaemia is greater when intracerebral haemorrhage is simulated by injection of blood into the basal ganglia than when an inert substance is injected. The implication is that cellular blood constituents themselves have an additional causal role in brain oedema. Our results lend support to these observations, in that global depletion of circulating leucocytes and platelets using whole body irradiation leads to less ischaemia and oedema in a rodent model of intracerebral haemorrhage. As the "haematoma" in this study is an inert mass the results suggest that the circulating leucocytes and

platelets have a role in generating oedema.

The observation that head only irradiation produced significantly greater oedema might be related to the leucocytosis found in this experimental group and support the hypothesis that leucocytes are implicated in oedema formation. Leucocytosis has been shown to be a risk factor for ischaemic complications following subarachnoid haemorrhage and a common pathway could be envisaged. That body only irradiation did not confer protection against oedema formation despite producing a similar reduction in platelets and leucocytes as whole body irradiation requires explanation. Although not statistically different, the mean values of leucocytes and platelet count were numerically greater in the body only irradiated group. A threshold level may exist for both cell counts, below which protection from oedema formation is conferred. Alternatively, the function of the circulating leucocytes and platelets may have been altered in the whole body irradiated group.33 In the body only group cells arising from the skull marrow would have normal function and undergo normal activation.34 A third possibility is that platelet depletion is the main factor in conferring protection. In the whole body group the platelet count continued to fall after creation of the lesion until the time oedema measurements were taken. This did not occur in the body only group (table 3).

Published data are conflicting on the role of leucocytes and platelets in mediating ischaemia and oedema formation. Both cell types accumulate in ischaemic brain.8 Limited data are available on the role of the individual leucocyte subgroups. Neutrophils have been most extensively investigated and have been implicated in the production of ischaemic damage in several organs.11-13 Some evidence exists that they contribute to ischaemic brain damage.14 However, neutrophil depletion with vinblastine has failed to show any beneficial effects in our model,35 and this observation has been supported by recent studies.36-38 In our study the lowest neutrophil counts were found in the whole body irradiated group and the highest counts in the head only irradiated group, which lends support to the hypothesis that the neutrophil has a role in oedema formation.

Lymphocytes have been shown to accumulate late in ischaemic brain.39 No data are available on their role in producing cerebral oedema. Interestingly, when ischaemic brain damage has been reduced by leucocyte depletion, the circulating lymphocyte count is reduced by over half.40 41 Similar large reductions in lymphocyte count were observed in the whole body and body only irradiated groups in this study. The immune system has been implicated in the production of vasospasm after subarachnoid haemorrhage40 and may be involved in the production of arterial spasm and ischaemia around an intracerebral haemorrhage. Cyclosporin, a potent immunosuppressant drug, has been shown to reduce vasospasm after experimental subarachnoid haemorrhage.41

Depletion of macrophages has been shown to be protective against ischaemic damage in a model of spinal injury.42 No data are available on their role in generating ischaemic damage in the brain.

Platelets accumulate in ischaemic brain.9 They are known to release a variety of vasoactive substances10 43-44 which can produce vascular and neuronal damage. Platelet activating factor may play a central role in producing oedema by linking the leucocyte mediated component with the platelet mediated damage. In the whole body irradiated group profound thrombocytopenia had occurred by the time oedema was measured. This did not occur in the body only irradiated group. This may explain why the body only irradiation did not protect against oedema formation despite causing comparable degrees of leucopenia.

In conclusion, depletion of circulating leucocytes and platelets by whole body irradiation confers protection against ischaemia and oedema, around an intracerebral haemorrhage. This was independent of any local effect of the irradiation. Current evidence is inconclusive on the nature of the cell types that may be involved in oedema formation. The multiplicity of active metabolites that can be released at the site of haemorrhage by leucocytes and platelets suggests that they all probably have a role and that oedema formation is not the “privilege” of a single blood cell type. The activity of the individual blood cell subgroups after intracerebral haemorrhage deserves further study.
