MECHANISMS OF CARBAMAZEPINE-INDUCED ANTIDIURESIS

Carbamazepine may cause water retention and hyponatremia. Indeed, the plasma osmolality with carbamazepine was found to be significantly lower than that with placebo. However, the mechanism of this effect is still unclear. In contrast, Goodman and Gilman's "The Pharmacological Basis of Therapeutics" notes that carbamazepine has an antidiuretic effect that is sometimes associated with a reduced AVP level and indicates that the mechanisms of water retention are not clearly understood. However, the "Martindale Extra Pharmacological" references note the antidiuretic effects of carbamazepine and support both central and renal mechanisms, clearly noting that carbamazepine sensitises the kidney to the effects of vasopressin.

The exact mode of action of carbamazepine is controversial. There is evidence that the drug may stimulate the central release of AVP either directly or by altering the threshold of the hypothalamic osmoreceptors, while others claim that it reduces the overall AVP level with carbamazepine treatment. The exact mechanism is not fully understood.

A reduction in vasopressinase activity is another possibility. These effects need not be mutually exclusive. The two case reports citing a central effect of carbamazepine found an AVP level with AVP treatment and during hyponatraemia but both were taken on other drugs.

Sorenson and Hammer found no change in the basal plasma AVP level with carbamazepine treatment. Despite this, the plasma osmolality with carbamazepine although the plasma osmolality had significantly decreased. This suggests a different renal response to the same AVP exposure and their conclusion that there was an AVP-secreting lesion is questionable. Meinders et al. had previously reported a fall in plasma AVP with carbamazepine treatment and having found an antidiuretic effect of the drug on patients with cranial diabetes insipidus, they concluded that the mode of action was renal and not central. When examining the relationships between plasma and urine sodium, osmolality, and AVP levels in normal subjects, Thomas et al. found that the slope of the regression line between plasma or urine AVP to urine osmolality was not increased by carbamazepine treatment. The drug did not result in a higher urine osmolality for a given amount of AVP. They also found that both plasma AVP concentration and urine AVP excretion rate were reduced by the drug and there was a significant rise in the plasma sodium compared with a control period. Having ruled out a direct renal and a central stimulatory effect on AVP secretion, they concluded that carbamazepine resets the osmotic threshold for AVP release without affecting osmotic control along the new threshold.

Yet they acknowledged that the mechanism for the production of carbamazepine-related hyponatraemia was unclear.

While studying carbamazepine effects in normal subjects, Thomas et al. found no direct stimulation of AVP secretion but in contrast to Thomas et al. they found that there was an increased renal sensitivity to AVP. The AVP values found at peak diuretic when taking the drug were similar to controls despite an impaired water handling. They also suggested that there was no increase in parvocorticotropin AVP secretion which was in dehydration but was in relative excess during water loading. AVP basal values were again lowered by the drug. When a patient with carbamazepine-related hyponatraemia was treated with demeclocycline, free water clearance rose despite an increase in plasma AVP, providing further support for a direct renal action of carbamazepine. Demeclocycline has been successfully used in a similar patient following the failure of phenytoin, water restriction and carbamazepine dose reduction to correct the hyponatraemia. Further recent evidence suggests that plasma AVP may be decreased by carbamazepine even though plasma osmolality and AVP normals are increased. This may indicate that carbamazepine has an AVP-like action or that it increases the sensitivity of the AVP receptor to its agonist in both the kidney and the corticotropic in the anterior pituitary. The standard textbooks should be modified to encompass the diversity of the individual response to carbamazepine evident in the literature.
is expedited by breathing oxygen, preferably under pressure.

The classical structural damage caused by carbon monoxide poisoning is a diffuse hypoxic cerebral injury leading to infarction. The most common lesions are of the pallidum bilaterally and are predominantly in the anterior two thirds, and probably result from the sensitivity of this functional end arterial area to hypoxaemia and hypotension. A unilateral pallidal lesion and marked asymmetrical white matter involvement has been described. The unique feature of our case is acute obstructive hydrocephalus associated with bilateral cerebellar swelling and compression of the fourth ventricle. No involvement of the globus pallidus and medial temporal lobes was seen. The precise cause of this cerebellar oedema is unknown, but could have been due to acidosis and hypoxaemia which are a common cause of widespread white matter oedema in CO poisoning. The hydrocephalus was of a transient nature since it subsided on medical therapy. Bilateral cerebellar oedema in acute carbon monoxide poisoning, presenting with acute hydrocephalus, has not been previously reported. It is important to be aware of this complication in the initial stages, as a CSF diversion procedure might be required if it does not respond to steroids.

Figure (a + b) CT scans showing hydrocephalus 24 hours after admission and resolution of hydrocephalus six weeks later.

Benign relapsing meningo-encephalomyelitis

Monteiro and Correia described a 16 year old man who presented with three attacks of meningo-myelitis over a period of six years. In the third attack he also had encephalitis. We describe a young woman with frequent, relapsing and remitting meningo-encephalomyelitis.

A 19 year old woman presented with a two week history of sore throat, frontal headache and sinus infection with arthralgia and myalgia. She had acute urinary retention, pyrexia and a major seizure. In the subsequent 20 months she has had a relapsing and remitting neurological illness, the relapses typically lasting 14 days. There have been continuous inflammatory changes in her CSF. Many of the relapses have been associated with pyrexia, and she has frequently demonstrated Hermitte's sign and Uhthoff's phenomenon. There have been numerous separate episodes of neurological signs indicating lesions involving the cauda equina on two occasions, the brainstem and cerebellum on four occasions, the spinal cord once, and the optic nerves bilaterally twice with three separate attacks of right optic neuritis. She had complex partial seizures and four major seizures controlled by treatment with carbamazepine. On first admission a 10 day course of ampicillin and tetracycline was prescribed without benefit. Subsequently she has been treated with maintenance low dose prednisolone and pulsed methyl prednisolone for relapses.

Normal investigations have included: a complete infectious disease screen for all bacterial, viral and fungal causes (HIV antibody testing on two separate occasions was negative); a complete immunological and connective tissue disease screen, serum angiotensin converting enzyme levels, liver biopsy, Kveim biopsy, chest radiographs, cerebral angiography and repeated CSF for IgG, oligoclonal bands and cytology. Her HLA type is A1, A2, B8, B18, DR3 and DR4.

The main abnormality of the CSF was a variable lymphocytic pleocytosis in 11 lumbar punctures (range 6–268 cells). On three occasions the CSF protein was raised (0·60–0·70 g/l). Glucose levels have been normal.

During a 20 month period, five MRI brain scans have been performed. The first, a month after the initial presentation was normal. The second, three months later, showed an area of high signal in the right cerebellar hemisphere on T2 images and correspondingly an area of low signal on the IR scan. At 12 months a third MRI showed several areas of increased signal on T2 images; in the left middle cerebellar peduncle extending into the anterior aspect of the left cerebellar hemisphere, with a corresponding area on the right side, and also on the medial aspect of the right temporal lobe. These areas enhanced with intravenous gadolinium. Sixteen months after presentation a fourth MRI showed widespread T2 increased signal changes localised in the left fronto-parietal area involving both white matter and cortex, the left optic tract, the right temporal lobe, the corpus callosum and the right brainstem, extending into the right cerebellar peduncle. The areas involved were more extensive than those seen previously. Her most recent MRI scan, three months later, showed further new gadolinium enhancing lesions in the right temporal and parietal lobes, with resolution of some of the other lesions seen on earlier scans. The new enhancing right parietal lesion (fig) was biopsied stereotactically. Histology was non-specific with an excess of astrocytes in the cortex and more prominent in the white matter; oedema, narrow perivascular cuffs of myelin pallor and small numbers of foamy macrophages.

Neurophysiological investigation showed that the previously abnormal visual evoked response (VERs) became normal following the first episode of bilateral optic neuritis. After further attacks of right optic neuritis,
Acute transient hydrocephalus in carbon monoxide poisoning: a case report.
