Cocaine induced chronic tics

Since the early 1980s, cocaine misuse has rapidly become more frequent with many users chronically taking large doses of this drug. Cocaine use has been increasingly associated with ischaemic stroke, subarachnoid and intracerebral haemorrhage, seizures, migraine-like headaches, toxic encephalopathies, a fatal condition resembling neuroleptic malignant syndrome, and dystonia during administration and after withdrawal. It is also a risk factor for neuroleptic induced dystonia. Some of these complica-
tions are caused by its powerful vascular constricting effect. It also exacerbates the multifocal motor and vocal tics that are part of Tourette's syndrome. The first two cases of transient (<4 months) new onset tic disorders were reported in 1990. We describe a third patient, with no per-
sonal or familial history of Tourette's syndrome, who developed cocaine induced chronic tics over two years.

A 35 year old right handed woman was admitted for investigation of movement dis-
orders which had developed over the two preceding years. She had an otherwise unre-
markable medical record and no family history of neurological disease. Her psychi-
tric history showed a personality disorder with aggressive hyperactivity and episode of depression with polydrug and alcohol misuse, having consumed marijuana, mescaline, LSD, and magic mushrooms from 12 to 17 years of age. There was no evidence of the development of obsessive compulsive disorder or tran-
sient tic in childhood. She admitted to binge drinking of alcohol as well as regular and exclusive use of cocaine from the past nine years. The patient took cocaine intranasally from 26 to 32 years of age, then she switched to "crack" for three years. She also took benzodiazepines during periods of cocaine abstinence. She elected the intravenous route on only one occasion. Her HIV serology test was negative two months previous. She came to us one month before admission. Her symptoms consisted mainly of nostril flaring, arm jerks, griri-
maces, shoulder shrugging, grunting, and head jerks that had progressively increased in frequency and severity. These move-
mens had not disappeared for more than a few hours since the onset. They were mostly brief and jerky but more prolonged move-
ments also occurred, and were exacerbated by anxiety or temporarily suppressed volun-
tarily (for example, when waiting for a job interview).

Neurological examination showed, in addition to the tics already described, a mild cogwheel rigidity of the right arm. Tics were prominent in either extremity. The patient had no other symptoms and was not taking medication. She presented an acute episode of exacerbation after her return from a weekend leave during which she used both alcohol and cocaine. She had complex tics with coordinated abnormal movements involving her entire body, including eye deviation and rolling, facial contortions, and plaintive vocal sounds. She was also hyperactive, impulsive, and mutilated herself (right fingers). The abnormal movements disappeared briefly (five minutes) when she ate, and decreased to the basal level after one day. Her routine blood biochemistry was nor-
mal, as was her EEG. Her CSF proteins were slightly increased (548 mg/l). A CSF

neurotransmitter study was not done. The CSF homovanillic acid (HVA) was 26-1 ng/ml, 5-hydroxyindoleacetic acid (5HIAA) was 16-9 ng/ml, and 3-methoxy-4-hydroxy-

phenyl-ethanol amine (MHPG) was 38-7 ng/ml (normal CSF values of biogenic amines were obtained in 15 age matched controls with lumbar disc herniations. These were: HVA 48-2 (SD 10-1) ng/ml, 5HIAA 22-8 (6-8) ng/ml, and MHPG 11-8 (5-4) ng/ml. 99mTc-HMPAO SPECT showed focal regional cerebral blood flow hyperperfusion in the bilateral anterofrontal and prerolandic gyri and parieto-occipital cortex, left temporal and cerebellar cortex, and right basal ganglia. Brain CT showed no focal or general atrophy. The only abnormality was dilatation and elonga-
tion of the right vertebral and basilar arter-
ies. Against medical advice, she refused treatment and hastily left the hospital two weeks after admission, during which tics were always present. Neuropsychological evaluation was incomplete and no firm con-
clusions could be drawn. Pascual-Leone and Dhuna reported two cases of transient new onset tic disorders after a high dose of cocaine in the habitual cocaine misusers. Neither had a personal or family history of tics. After taking an unusu-
ally high dose of cocaine, these two patients presented multifocal motor and vocal tics. The tics resolved over several weeks to four months.2 Our patient seems to be the first case who developed new onset tics after intravenously taking a high dose of cocaine. These two women presented multifocal motor and vocal tics with chronic cocaine misuse. She took many other drugs from age 12 to 17, but her consumption of cocaine was virtually limited to cocaine intranasally from 26 to 35 (intravenously for six years and "crack" cocaine for three years). Alcohol (which is also misused by our patient) misuse or alco-
hol withdrawal is not associated with tics. The first woman is well known since her tics patient the tics were clearly exacerbated by high dose cocaine use. The hyperactivity syndrome presented in the past by our patient could be related to Tourette's syn-
drome and could represent an alternative phenotype for the putative Tourette's syn-
drome gene that might have been predis-
posing this patient to cocaine. This remains speculative, however.

In our patient SPECT showed multifocal abnormalities of regional cerebral blood flow. This may represent the consequence of regional functional damage, directly or indirectly related to brain imaging findings, or may represent the consequence of the pharmacodynamic effect of cocaine misusers. Neither had a personal or family history of tics. After taking an unusually high dose of cocaine, these two women presented multifocal motor and vocal tics. The tics resolved over several weeks to four months.2 Our patient seems to be the first case who developed new onset tics after intravenously taking a high dose of cocaine. aggravate pre-existent movement disorders such as Tourette’s syndrome and chorea,1 or provoke tics in patients with attention deficit hyperactivity disorders.5 These amphetamine mediated phenomena are similar to those induced by cocaine except for the stereotopic dyskinesia. In regard to the NAcergic system, there were no biochemical abnormalities in the cortex and basal ganglia.5 Clonidine, an α2-adrenergic agonist, reduced tics, however, through a direct effect on GABA neurotransmitter systems that is only partially detected by GABA metabolism. Some findings (cited by Lang6) reported variable implications of opioid and GABAergic systems in the pathogenesis of Tourette’s syndrome. Opiate antagonists may lessen tics, whereas withdrawal of chronic opiate treatment may worsen this condition. There are some responses to benzodiazepines (clonazepam). Implications of other neurotransmitter systems are cited in the literature but these findings are not consistent.7 Further controlled studies using SPECT or PET, CSF biogenic amines, possibly concentrations of cocaine in blood or CSF, and neuropsychological testing results are needed to better identify deficiencies after cocaine misuse.

A 65 year old ex-policeman was admitted with a three day history of falling to his right whenever he attempted to sit, stand, or walk. He was normal until a day before the onset of this neurological event when he had complained of a mild generalised throbbing headache. The next morning he noticed difficulty in getting out of bed and needed support to even sit erect. He was unable to stand or walk without support. Whenever he attempted to do so he leaned heavily to his right and fell over. He had never experienced such an event in the past. There was no history of drugs that could produce extrapyramidal syndrome or ataxia. He gave no history of head trauma. He was not a diabetic and was not hypertensive.

On admission his blood pressure was 140/80 mmHg and his heart rate was 90 beats/min. The cardiovascular system was normal. There were no external injuries. He was conscious and well orientated to his surroundings. Speech and memory were normal. His pupils were normal in size and reacted equally well to light. He had a mild drift of the outstretched right arm. Power of the other limbs was normal. Muscle tone was normal in all limbs. The deep tendon reflexes were hyperactive on the left side. The Babinski’s reflex was flexor on both sides.

His tendency to fall to his right was obvious and striking. He was unable to sit, stand, or walk without support. When asked to rise from a recumbent posture he would grapple at the cot railings with his left hand and struggle to do so. When supported he could sit erect for a few seconds but gradually leaned to his right and diagonally backwards. When helped to stand erect, he would fall in the same direction. Supported walking was possible for only a few steps and was terminated by the falling attack. Another striking feature was that he made no postural adjustments to overcome such falls and barely expressed concern about them (figure; left).

He had no evidence of hemianesthesia or visual field cut. Bedside tests for sensory neglect were negative. His right arm was underused in motor tasks. This was out of proportion to the mild weakness of that limb, indicating presence of motor neglect as well as the pyramidal lesion. He had no features of cerebellar, vestibular, or peripheral nerve disorder.

A clinical diagnosis of “ease of falling” syndrome was made. A plain and contrast enhanced CT of the head surprisingly showed a large subdural haematoma in the left frontoparietal region (figure; right). The haematoma was isodense with the cortex and compressed the ipsilateral subcortical structures and lateral ventricle and produced a shift of the midline structures to the opposite side. There was no evidence of damage to the underlying brain. Chest radiograph, BCG, and carotid Doppler studies were normal. Blood chemistry was normal. Serumological tests for syphilis were negative.

A burrhole was made on the left side of the skull and 250 ml of altered blood was evacuated under local anaesthesia. The result was dramatic. The patient could sit erect without support in the immediate postoperative hours. Detailed evaluation was carried out over the next 24 hours and photographically documented. He could sit erect, stand, and walk by himself without any tendency to fall. The outstretched right arm showed no drift. The pyramidal signs and motor neglect disappeared.

The “ease of falling” syndrome has become well characterised through the studies of Masdeu and Gorelick,2 Awerbuch et al4, and Labadie et al6. Isolated cases with similar features had already been reported by Fisher and Cole in 1965 and by Fisher in 1979 and 1982.2,13 As noted by all these authors the falls are a contralateral slow tilting motion either laterally or diagonally backwards. The patient shows lack of awareness and does not make postural adjustments to avoid the fall. Criteria require that the patient should exhibit such falling events in the absence of significant hemiparesis, hemianesthesia, cerebellar, ataxia, vestibular dysfunction, proprioceptive loss, and peripheral nerve disorder. Our patient qualifies for the diagnosis of this syndrome.

All previously reported cases had an intracerebral lesion affecting either the putamen, pallidum, or the thalamus, Lacunar infarcts and haemorrhages are the only lesions that have produced this acute

“Ease of falling” syndrome associated with subdural haematoma

The “ease of falling” syndrome refers to acute onset contralateral postural deficits secondary to acute lesions of the unilateral basal ganglia. Previously reported cases4,6 had intracerebral lesions affecting the basal ganglia. The present case is unique as the patient developed the syndrome secondary to an extracerebral lesion in the form of a subdural haematoma.

(left) The patient falling to his right and diagonally backwards. Note the lack of concern about the fall; (right) CT showing a large left frontoparietal subdural haematoma.
Cocaine induced chronic tics.
