Machado-Joseph disease presenting as severe asymmetric proximal neuropathy

I N van Schaik, G J Jöbsis, M Vermeulen, H Keizers, P A Bolhuis, M de Visser

Abstract
Despite much effort, a 74 year old man with progressive proximal weakness and sensory disturbances due to axonal neuropathy remained a diagnostic problem. Investigation of his family disclosed an additional patient with a cerebellar syndrome and a family member with mainly pyramidal features. Analysis of DNA showed a CAG repeat expansion in the Machado-Joseph disease gene in all three patients. Although not conclusively proved, we think that the neuropathy of the index case is linked to the CAG repeat expansion. Machado-Joseph disease should be considered in progressive axonal neuropathy.

Case summaries
The proband, patient A (figure), a 74 year old man of Dutch descent developed difficulty walking at the age of 50 due to buckling of his left knee. Subsequently, in the course of two decades, weakness spread to his left arm, right leg, and finally his right arm. At the age of 73 he became confined to a wheelchair and needed assistance for normal daily activities. He experienced pins and needles with numbness of the left arm and altered temperature sensation of the lower limbs with periods of burning feet. Medical history disclosed non-insulin dependent diabetes mellitus for the past two years, hypertension, myocardial infarction, a left-sided total hip replacement, and meniscectomy. Medication consisted of metoprolol, triamterene, hydrochlorothiazide, tolbutamide, and calcium carbasalate.

On examination there were cold, bluish discoloured legs with pitting oedema; absence of normal cranial nerve signs except for saccadic eye movement on pursuit; fasciculations of arm muscles; generalised atrophy, especially of the proximal muscles and more severe on the left; severe paresis of the left leg (grade 2-3 on MRC scale); and paresis of the other limbs, proximal grade 3-4 and distal grade 4. Sensory deficit consisted of diminished sensation to pain and light touch in the left arm and diminished vibration and position sense of the entire lower limbs. There was areflexia except for the...
tendon reflexes of the right arm and plantar responses were flexor.

Extensive laboratory investigation was unremarkable except for an IgG-κ paraproteinaemia which was classified as a monoclonal gammopathy of undetermined significance (MGUS). Antibodies against myelin associated glycoprotein and GM1-gangliosides were absent. Magnetic resonance imaging showed slight atrophy of the cerebellum, cerebrum, and cervical spinal cord but not of the brainstem and was otherwise normal. Electrophysiological studies disclosed decreased compound muscle action potentials (CMAPs), decreased sensory nerve action potentials (SNAPs), and slightly delayed nerve conduction velocities in the upper and lower limbs (table). The peroneal CMAP and left sided sural SNAPs were absent. Electromyography showed signs of severe denervation and reinnervation. These findings were considered to be consistent with axonal motor-sensory neuropathy. Visual and brainstem auditory evoked potentials were normal, eye movement recording showed square wave jerks and saccadic pursuit. With magnetic stimulation no central conduction disturbance of motor neurons was found. Biopsy of the quadriceps muscle showed chronic and active denervation atrophy with some rimmed vacuoles and sarcoplasmic glycogen masses. An ischaemic forearm test disclosed a normal increase of lactate after exercise. Sural nerve biopsy showed chronic axonal degeneration with signs of regeneration and extensive loss of both myelinated and unmyelinated fibres. The large myelinated fibres were nearly absent in the unimodal histogram. Immunohistochemical techniques did not show IgG or complement deposits. Staining for leucocyte markers showed some cells scattered throughout the epineurium and perineurium. There were no signs of active inflammation. Ten months after examination he died at home during his sleep due to an unknown cause. Permission for necropsy was not given by his family.

A younger brother of the proband (patient B), a 72 year old man with progressive walking difficulty for at least 10 years, displayed on examination cerebellar features such as gait ataxia, dysarthria, and saccadic eye movements on pursuit. Except for diminished vibration sense of the feet, there were no sensory signs or upper motor signs. The ankle and knee jerks were absent. Brain MRI showed atrophy of cerebellum and brainstem. Eye movement recording showed spontaneous nystagmus, abnormal smooth pursuit, and diminished vestibulo-ocular and caloric nystagmus.

Patient C, a 29 year old son of patient B with symptoms of clumsiness and stiffness, had spasticity in addition to nystagmus, saccadic eye movements, and dysdiadochokinesia.

The figure shows additional family members neurologically examined.

### Methods and results of genetic analysis

DNA was obtained by extraction from leucocytes using standard methods. The Machado-Joseph disease CAG repeat was amplified by polymerase chain reaction from genomic DNA as described elsewhere. The size of the CAG repeat was determined by polyacrylamide/urea/formamide gel electrophoresis using a sequence ladder as a length marker. Determinations of CAG repeat length showed a repeat number (including one interspersed CAA) of 22 and 54 for patient A, 22 and 62 for patient B, and 22 and 68 for patient C.

### Discussion

Although the index case with severe, asymmetric, proximal motor-sensory neuropathy is not suggestive of Machado-Joseph disease, this...
diagnosis was finally considered most likely. The family contained additional members with longstanding neurological complaints; these relatives were either unavailable or clinical investigation or DNA analysis showed that they did not have Machado-Joseph disease. The index patient had had non-insulin dependent diabetes mellitus for two years which was well regulated with an oral antidiabetic drug. His neurological symptoms started long before the diabetes was diagnosed. Moreover, the type of neuropathy, distribution of signs and symptoms, and the neurophysiological and pathological findings are not consistent with any of the known diabetic neuropathy syndromes. The same holds true for the IgG monoclonal gammopathy of undetermined significance (MGUS). Neuropathies associated with IgG MGUS are normally symmetric, slowly progressive, and never lead to complete paralysis or respiratory failure. Neurophysiological studies show segmental demyelination and nerve biopsies often show deposits of immunoglobulins in the peripheral nerve; both features were absent in the index case.

The repeat length of 54 CAGs of patient A is below the smallest repeat expansion reported for Machado-Joseph disease so far—that is, 61.15,16 In view of the correlation between repeat number and phenotype,7,17 it is tempting to speculate that the atypical presentation of the index case is related to the short repeat expansion.

Machado-Joseph disease has been considered to be distinct from autosomal dominant cerebellar ataxia type I (ADCA I, reviewed by Junck and Fink).14 Characteristics that seemed to separate Machado-Joseph disease included clinical signs (faciolingual contraction fasciculations and pseudosexphalthamus), distribution of pathology (sparing of the inferior olivary nucleus and substantia nigra), and the nearly exclusive occurrence in people of Portuguese or Azorean descent. Recently, the genetic defect of Machado-Joseph disease was found to be identical to a subset of ADCA I—that is, spinocerebellar ataxia type 3 (SCA3).15,17-18 Several hypothetical mechanisms could account for a mutation giving rise to two disorders or various phenotypes within one disorder.14 Alternatively, contrary to previous classification systems the most common type of Machado-Joseph disease with mainly cerebellar features might be identical to SCA3. Other types of Machado-Joseph disease should be present in ADCA I/SCA3 families as well.

This Dutch family has three presentation forms: atrophy with neuropathy, cerebellar ataxia, and spasticity. Our findings sustain the presence of an age related presentation in west European, non-Portuguese/non-Azorean ADCA I with the Machado-Joseph disease/SCA3 repeat expansion. If, despite a shared mutation, the particular features of Machado-Joseph disease such as the age related presenta-

tion are taken to constitute sufficient grounds to distinguish it from SCA3, our kindred shows that Machado-Joseph disease is also present in patients of Diabat dior. Whatever the outcome of the nosological debate, Machado-Joseph disease/SCA3 should be considered in severe, progressive proximal axonal neuropathy, especially if the family history shows relatives with a cerebellar syndrome. In a heterogeneous group of disorders with a highly variable presentation like ADCA I, DNA analysis will help to delineate the nosological boundaries. The range of phenotypes in Machado-Joseph disease could become larger when CAG repeat expansions are systematically sought in families with neurodegenerative diseases of unknown origin.

This work was supported in part by grants from the Schuhmacher-Kramer foundation and the Princes Beatrix Fonds. JvD and GJF contributed equally to this study. We are grateful to Dr AAWM Gabreëls-Festen for assessment of the sural nerve biopsy and Dr R Witteveen for referral of the index patient.
