Selective sparing of topographical memory

Eleanor A Maguire, Lisa Cipolotti

Abstract

The case of a 61 year old patient with Pick’s disease involving predominantly the left temporal lobe, who has been studied over a 5 year period, is reported. She presented with a grave impairment of both verbal and non-verbal memory functions. Her non-verbal memory deficits included profound impairments on the recognition of unfamiliar faces and the recall of abstract designs. Remarkably, her visual recognition memory performance for unfamiliar buildings, landscapes, and outdoor scenes was preserved. Strikingly, her ability to recall familiar routes and learn new ones through a complex virtual reality town was also entirely normal. This seems to be the first case documenting the selective preservation of topographical memory in the context of severe non-verbal and verbal memory impairments. These findings imply that topographical memory and non-verbal memory are subserved by separable neural systems.

Keywords: topographical memory; Pick’s disease; selective preservation

It is widely acknowledged that unilateral damage to the medial temporal lobe can result in modality specific memory impairments. Typically, right medial temporal lobe lesions result selectively in non-verbal memory deficits whereas left medial temporal lobe lesions result in verbal memory impairments. Often patients with damage to the right temporal lobe present a non-verbal memory impairment that encompasses poor performance on tests employing various visual memoranda such as the recall of abstract designs, the processing of topographical stimuli, and the recognition of unfamiliar faces. However, the extent to which non-verbal memory impairments can be selectively limited to one class of stimuli has been relatively little investigated. For example, patients have been reported with impairments in memory for abstract visual and spatial designs. However, it remains unclear whether topographical memoranda are processed by the same pathway as other non-face visual stimuli—such as abstract visual designs—or whether they are processed by an encapsulated pathway as are faces.

In this study we document for the first time the selective sparing of topographical memory in a patient with Pick’s disease. This patient presented with a severe verbal memory impairment affecting both recognition and recall. In addition, she presented a profound non-verbal memory impairment for stimuli including unfamiliar faces and abstract visual designs.

Case report

The patient was a 61 year old right handed teacher who was first referred to Dr Zilkha in 1992 with a 1 year history of word finding difficulties. Neurological examination was entirely normal except for the cognitive deficit described below. Brain MRI contemporaneous with her final neuropsychological assessment showed generalised cerebral atrophy, particularly marked in the left temporal lobe and...
involving all left temporal gyri and medial structures. The atrophic changes in the right temporal cortex were considerably less marked than in the left temporal lobe, and commensurate with those seen generally. In comparing the left and right temporal cortex, the atrophic changes on the right did not extend as posteriorly as those on the left. The right medial temporal structures were also clearly less affected than the left medial temporal structures (figure). The clinical diagnosis was probable Pick’s disease.

NEUROPSYCHOLOGICAL ASSESSMENT

The patient was first referred to the Neuropsychology Department of the National Hospital for Neurology and Neurosurgery in December 1992 for evaluation of her language difficulties. She has been subsequently reassessed on five occasions. The detailed topographical memory investigation reported here took place at the time of her fifth assessment (April 1997). The results of her five formal neuropsychological assessments are reported in table 1.

When she was first assessed on the Wechsler adult intelligence scale (WAIS-R) in December 1992 her verbal and performance IQs were average. However, in view of her occupational and educational record, these figures were clearly below her estimated premorbid optimal level of functioning. Her verbal memory functions were found to be selectively weak when compared with her superior visual memory functions. There was also some evidence of word finding difficulties. On the graded naming test her performance was slow, effortful, and in the low average range. However, her visual perceptual functions, as assessed by subtests of the visual object space perception battery, were within the normal range.

Through the second, third, and fourth assessments, her verbal skills deteriorated steadily while her non-verbal cognitive skills remained static at an average level. The two

most notable features were her increasingly severe word finding difficulties and the selective and severe progressive decline of her verbal memory functions. At the time of her fifth neuropsychological assessment, a further decline in her cognitive status was noted. There had been a further significant decline in her verbal IQ, now at a defective level. By contrast, her performance IQ had remained at an average level. Her spontaneous speech was very sparse, marred by profound nominal impairments. She was now virtually unable to orally name to confrontation. Her comprehension at the single word level was assessed on a stringent written two choice synonym test for concrete and abstract words. She obtained a low average score on this test. Her performance on tests of perception and spatial skills remained at a normal level.

Although there was evidence of a selective verbal memory impairment on the first four assessments, at the time of the fifth assessment a more severe global memory impairment was recorded (table 1). Her performance was found to be severely impaired on a recognition memory task using unfamiliar faces. This impairment was not underpinned by a more general deficit in face processing; she was able to recognise photographs of famous faces fluently (12/12).

MEMORY INVESTIGATIONS

At the time of her fifth neuropsychological assessment the patient was still able to attend regular hospital appointments making a long and complicated journey on her own. Often at the end of her hospital appointment she would successfully visit unaccompanied various museums and art exhibitions in London. In addition, she had no difficulty orienting herself within the hospital environment. Indeed, she learned two new routes taking her between departments very rapidly. She still drove her car and could easily learn new routes when driving her husband for weekend trips. These observations clearly contrasted with the finding of a severe and global memory impairment. To explore her memory functions further, the following tests using verbal and visual stimuli, some of which were specifically topographical, were completed.

CONTROL SUBJECTS

Six normal healthy women of comparable age (range 46–57 years) and education (to degree level) to our patient were used as controls on some of the memory tests described below.

RECALL MEMORY FOR WORDS AND VISUAL STIMULI

A verbal and a non-verbal recall task were administered to the patient. The verbal recall memory test was the easy paired associates learning test devised by Clegg and Warrington. The visual recall memory test was the Rey-Osterreith complex figure. Her results are reported in table 2. Her performance was gravely impaired on both an alternative version of the recognition memory test and on the easy version of the recognition memory test. This impairment equally affected memory for words and faces. These findings provide a very robust replication of our original finding and suggest that the patient had a grave verbal and non-verbal memory impairment.

SPATIAL LEARNING

Spatial span was assessed with the Corsi block tapping task which required the patient to tap wooden blocks randomly arranged on a tablet in the same order as tapped by the examiner. On this task her performance was well within the normal range (spatial span seven blocks). After having established her short term memory spatial span, learning was assessed by presenting a supraspan sequence repeatedly (span+two=nine blocks), as described by De Renzi et al. She learned the sequence in 16 trials, which is well within the average of the normal control group reported by De Renzi et al.

MAZES

The patient was also given a visual maze task. Maze number 7 from the Wechsler intelligence scale for children (WISC-R) was employed. She was requested to trace the path to the exit as quickly as possible. The same maze was repeatedly presented. Her completion time was recorded with a stopwatch. The patient’s significant global cognitive impairment and perseverative tendencies meant that it took several attempts to explain the task so that she understood what was required. Her dyspraxia also contributed to a slowing of performance. However, given these limitations, she performed satisfactorily, showing increasingly shorter completion times. It took her 5 minutes

35 seconds to complete the first trial. However, at the time of the sixth trial her completion time was only 25 seconds, indicating that she presented with no gross deficit on this measure.

**TOPOGRAPHICAL MEMORY**

**Recognition memory for topographical scenes, unknown buildings, and landscapes**

The patient was tested on three recognition memory tests each involving topographical memory. These tests were devised to be comparable with the recognition memory test for words and faces but varied in the material and number of items employed. In the topographical recognition memory test, the memoranda are 30 coloured photographs of outdoor topographical scenes. Three alternative forced choice recognition memory tests followed with distractors showing the same scene as the target but from a different angle. This test is known to be sensitive to right hemispheric lesions. The recognition memory test for unknown buildings has been previously described by Whiteley and Warrington.17 The test consists of 50 black and white photographs of previously unknown buildings which are presented to the patient singly at a 3 second rate, the subject responding “yes” or “no” to each according to whether she liked the architecture or not. Two alternative forced choice recognition memory tests follow. This time the distractor item is a different building from the target but one which is architecturally similar to it. The recognition memory for unknown landscapes test is similar in structure and method of administration to the unknown buildings test. It differs in the patient’s orientation task and in the material. The memoranda in this task consist of black and white photographs of country scenes which vary from aerial views of coastlines to valleys, mountains, lakes, and rivers (for further details see Whiteley and Warrington”). The patient responded “yes” or “no” to each photograph according to whether she thought it has been taken in winter or in summer. The patient’s performance and the mean scores and range of controls are reported in table 3.

Remarkably, her performance on these tests was very good indeed. She obtained a superior score on the topographical recognition memory test. In addition, her performance was well within the normal range on the recognition memory tests for unknown buildings and landscapes. These results show that the patient’s topographical memory skills are far superior to her gravely impaired non-verbal and verbal memory skills.

**Routes: virtual reality town**

The topographical memory tests described above, although able to capture some aspects of real world topography, were clearly not designed to assess the dynamic aspects of topographical memory—namely, navigation. The patient’s ability to navigate to remembered locations was tested using a computer simulated town (designed by N Burgess; see Maguire et al26 for details). She sat in front of a computer monitor which displayed a colour, textured, first person view of a town. She navigated through the town using four keys on the computer keyboard (up, down, left, right). The town contained several streets and numerous buildings—two shops, a church, a large cinema complex, two bars, a train station, an amusement arcade, and a bank. She explored outside and inside all of the buildings, which were interconnected in different ways. She explored the town for as long as she needed so that she felt confident that she knew her way around. After learning, her ability to find her way in the town was tested. She was shown a picture of a place in the town and starting from a different place in the town, she had to find her way to the goal place using the four keys to navigate. During memory testing she was given a total of 10 places to find. Remarkably, her performance on this test was well within the range of our control subjects (table 3). Strikingly, at the end of the testing session, she was also able to draw an accurate map of the broad layout of the town that could be usefully followed by someone unfamiliar with the area.

Thus the patient not only presented with a selective preservation of topographical memory as assessed by static recognition memory tests, but also showed an intact capacity to engage in dynamic and successful navigation in complex environments.

**Geographical knowledge**

Geographical knowledge was tested in the patient. An initial investigation focused on her knowledge of geographical location. Four geographical location tests were administered: (1) famous London landmarks; (2) United Kingdom cities; (3) European cities; (4) world cities. For each of these four tests, a blank map was placed in front of the patient and she was asked to indicate the relevant locations by pointing. The mean score and the range of performance of the patient and the control women are presented in table 3. Her scores were well within the control range on the tests of London landmark location and at the lower limit of the control range for United Kingdom cities. By contrast, however, her locating of cities on blank maps of Europe and the world was deficient relative to the control subjects. It is of interest to note that out of the 18 errors made on these last two tests, only four involved misplacing of cities outside of Whiteley and Warrington’s 17 tests for unknown buildings has been previously described by Whiteley and Warrington17. The recognition memory for unknown buildings and landscapes described by Whiteley and Warrington17. The patient responded “yes” or “no” to each photograph according to whether she liked the architecture or not. Two alternative forced choice recognition memory tests follow. This time the distractor item is a different building from the target but one which is architecturally similar to it. The recognition memory for unknown landscapes test is similar in structure and method of administration to the unknown buildings test. It differs in the patient’s orientation task and in the material. The memoranda in this task consist of black and white photographs of country scenes which vary from aerial views of coastlines to valleys, mountains, lakes, and rivers (for further details see Whiteley and Warrington”). The patient responded “yes” or “no” to each photograph according to whether she thought it has been taken in winter or in summer. The patient’s performance and the mean scores and range of controls are reported in table 3. Remarkably, her performance on these tests was very good indeed. She obtained a superior score on the topographical recognition memory test. In addition, her performance was well within the normal range on the recognition memory tests for unknown buildings and landscapes. These results show that the patient’s topographical memory skills are far superior to her gravely impaired non-verbal and verbal memory skills.

**Routes: virtual reality town**

The topographical memory tests described above, although able to capture some aspects of real world topography, were clearly not designed to assess the dynamic aspects of topographical memory—namely, navigation. The patient’s ability to navigate to remembered locations was tested using a computer simulated town (designed by N Burgess; see Maguire et al26 for details). She sat in front of a computer monitor which displayed a colour, textured, first person view of a town. She navigated through the town using four keys on the computer keyboard (up, down, left, right). The town contained several streets and numerous buildings—two shops, a church, a large cinema complex, two bars, a train station, an amusement arcade, and a bank. She explored outside and inside all of the buildings, which were interconnected in different ways. She explored the town for as long as she needed so that she felt confident that she knew her way around. After learning, her ability to find her way in the town was tested. She was shown a picture of a place in the town and starting from a different place in the town, she had to find her way to the goal place using the four keys to navigate. During memory testing she was given a total of 10 places to find. Remarkably, her performance on this test was well within the range of our control subjects (table 3). Strikingly, at the end of the testing session, she was also able to draw an accurate map of the broad layout of the town that could be usefully followed by someone unfamiliar with the area.

Thus the patient not only presented with a selective preservation of topographical memory as assessed by static recognition memory tests, but also showed an intact capacity to engage in dynamic and successful navigation in complex environments.

**Geographical knowledge**

Geographical knowledge was tested in the patient. An initial investigation focused on her knowledge of geographical location. Four geographical location tests were administered: (1) famous London landmarks; (2) United Kingdom cities; (3) European cities; (4) world cities. For each of these four tests, a blank map was placed in front of the patient and she was asked to indicate the relevant locations by pointing. The mean score and the range of performance of the patient and the control women are presented in table 3. Her scores were well within the control range on the tests of London landmark location and at the lower limit of the control range for United Kingdom cities. By contrast, however, her locating of cities on blank maps of Europe and the world was deficient relative to the control subjects. It is of interest to note that out of the 18 errors made on these last two tests, only four involved misplacing of cities outside of
Selective sparing of topographical memory

their correct country boundaries. For example, when asked to indicate the location of the city of Los Angeles, she pointed to a location within the correct country (United States) but incorrectly on the east coast instead of the west. This suggests that she had preserved knowledge at a level superordinate to the specific locations of cities.

Further testing focused on the patient’s knowledge of geographical direction (table 3). Two tests of geographical direction were administered: (1) north/south United Kingdom cities; (2) north/south world cities. Testing in both cases involved two cards being placed in front of her, one depicting the word “north” and the other the word “south”. In the north/south United Kingdom cities test, cards with names of British cities were shown to her one at a time. She was required to indicate whether the city was north or south of London by placing the name of the city under the name of the card north or south. In the north/south world cities test, she was asked to indicate if well known world cities were north or south of England by placing city names under the north/south cards. Confirming the differential performance noted in the four geographical location tests outlined above, her performance was at the lower limits of the control range for the English cities but clearly more impaired for world cities.

Discussion
In this study we have described an investigation of the memory skills of a patient with Pick’s disease who has been followed up over a 5 year period. The topographical memory investigations reported here were carried out at the time of her fifth assessment. By this time, she was exhibiting a grave impairment of language; she had very sparse spontaneous speech, was virtually unable to name to confrontation, and had mild word comprehension difficulties. Her memory functions, which had originally been characterised by a selective loss of verbal memory, had progressively deteriorated to become globally and gravely affected for verbal and non-verbal material at the time of this report. Her performance was profoundly impaired on three tests of varying difficulty of recognition memory for words and on a verbal recall memory test. Similarly, on three tests of varying difficulty of recognition memory for unfamiliar faces her performance was severely impaired. Her visual memory recall as indexed by the Rey-Osterreith complex figure test was also impaired. Her severe non-verbal memory impairment affecting both recognition and recall could not be accounted for in terms of more general visuo perceptual or face processing deficits. Indeed, she had normal performance on visuo perceptual tests, produced a perfect copy of the Rey-Osterreith complex figure, and flawless performance on a test of famous face identification.

In the midst of her profound verbal and non-verbal memory impairments, her recognition memory performance for topographical scenes, unknown buildings, and landscapes was remarkably intact. Moreover, her ability to recall familiar routes and learn new ones through a complex virtual reality town was also normal. Her spatial learning skills and maze performance were also preserved. Despite preservation of many aspects of topographical memory, intact geographical knowledge was restricted only to the United Kingdom.

As far as we are aware, this study is the first to document the sparing of topographical memory in the context of profound non-verbal memory loss which includes both recognition memory for unfamiliar faces and recall of an abstract visual design. These findings support the notion that topographical memory is subserved by a system separable from that serving the memory for unfamiliar faces and abstract visual designs.

At the first analysis, it is not immediately clear why such differential patterns of performance are seen across tasks that might be thought to have similar visuo perceptual and spatial requirements. For example, memory for a complex abstract visual design requires visuo perceptual analysis and the processing and recall of spatial relations. Arguably, these abilities are required to an even greater extent in the learning of new routes. Despite this, the patient could not recall an abstract visual design, but quite clearly had no difficulty in recalling routes she had travelled, or in learning new routes. It is possible that her locomotion along and experience of local or national routes recruits a specialised processing channel that integrates visual and somaesthetic information about large topographical items, perhaps in an allocentric (world centred) spatial framework. Recall of abstract visual designs is possibly processed by a different system concerned with the egocentric (person centred) manipulation of spatial configurations or icons that are essentially devoid of real world experience.

From this position, it could be argued that topographical scenes (particularly unfamiliar), buildings, and landscapes are complex designs that should be processed as egocentric configurations and so be impaired in our patient. However, these topographical stimuli represent important anchor items that facilitate the construction and use of a “cognitive map” of a spatially extended area. In line with this, cognitive models of environmental learning commonly ascribe a significant role to buildings and landmarks as initial anchor points in topographical memory development. For example, it has been shown that topographical stimuli play a crucial part in route learning because effectively they specify the person’s location. Thus we could speculate that topographical scenes, buildings, and landmarks activate important aspects of the topographical memory system in a similar manner to the recall and learning of complex routes. As the patient can process routes, she can use the same system to also process topographical stimuli.

A recent functional neuroimaging study found evidence in support of the position that landmarks activate most of the topographical memory circuit that is also activated by the
memory for complex routes. Maguire et al33 measured changes in rCBF (regional cerebral blood flow) with PET while subjects recalled familiar routes around London in one task, and while recalling famous world landmarks in another. Importantly, the landmarks that were recalled were ones that the subjects were familiar with but had never visited, so landmark recall was not confounded by location information about position within a large scale spatial layout. They found that the pattern of increased brain activity associated with the recall of routes and landmarks was very similar. This included extrastriate regions, bilateral occipitotemporal areas, and bilateral parahippocampal gyrus activation. The involvement of common brain regions in routes and landmarks memory suggests that the same topographical memory system is activated when processing both routes and landmarks.

Given our patient’s preserved topographical memory skills, how can we account for her pattern of performance on geographical knowledge tests? In the context of the limited amount of testing carried out, her severe language and verbal memory impairments and the limited amount of information available regarding her premorbid knowledge of the places considered, we merely offer a tentative suggestion. We have argued that our patient remains capable of utilising a system that integrates information about large topographical items as a consequence of locomotion around these objects. The preservation of this system may explain the patient’s intact performance on the location of London landmarks test; she is likely to have visited most of these landmarks. From this position, it might be suggested that the patient would be severely impaired in locating cities within countries; it is unlikely that the representation of these items could be achieved during locomotion.16 In line with this, the patient was certainly severely impaired on city location in Europe and the world, and on the north/south world test. She performed at the lower limit of the control range for both city location in the United Kingdom and the north/south United Kingdom test. This pattern of apparent preservation is difficult to interpret. It is possible that her performance was affected by an interaction between the relatively few stimuli used and the relative insensitivity of these measures. Unfortunately a more far reaching examination of these issues was precluded in this case.

The neuropsychological literature has often15 16 19 32 implicated the right medial temporal region in mediating topographical memory. In a recent paper, McCarthy et al33 speculated that the storage and processing of place knowledge may be closely linked with spatial skills dependent on the right hemisphere. Functional brain imaging studies using PET and functional MRI in neurologically intact people, have confirmed that there is significant neuronal response in the right medial temporal region during topographical memory tasks.26 35 36 38 Neuroradiological findings in our patient show a marked contrast between her left and right medial temporal lobes. The left temporal lobe is grossly atrophic relative to the right. The right temporal lobe seems less affected particularly in the medial and more posterior regions. These findings are compatible with the literature on the anatomy of topographical memory.

In conclusion, this study shows the complete dissociability of topographical memory from verbal memory. Moreover, it seems that the neural system which is responsible for implementing topographical memory is independent of that implementing other aspects of non-verbal memory such as unfamiliar faces and abstract visual designs. Moscovitch and Umiltà39 have suggested that the investigation of the selectivity of preservation of cognitive functions, in this case topographical memory, allows the determination of its degree of information encapsulation. Our findings are compatible with the notion that topographical memory is an information encapsulated module distinct and separable from the non-verbal memory systems involved in unfamiliar faces and abstract designs. Given the critical necessity of navigating in the world for both humans and animals, it is perhaps not surprising that topographical memory can continue to operate despite the malfunctioning of a central repository of general knowledge.

We thank Dr Martin Rosser for his permission to study this patient who was under his care. We are also grateful to Drs Neil Burgess and Jim Donnett, and Professor John O’Keefe for their work on computer simulated environments. We thank Professors C Frith and T Shallice, and Dr P Rudge for helpful comments. We also thank N Smith for collecting control data. EAM is supported by the Wellcome Trust.

Selective sparing of topographical memory
