Pain after whiplash: a prospective controlled inception cohort study

Diana Obelieniene, Harald Schrader, Gunnar Bovim, Irena Misevičienė, Trond Sand

Abstract

Objectives—In Lithuania, there is little awareness of the notion that chronic symptoms may result from rear end collisions via the so-called whiplash injury. After most such collisions no contact with the health service is established. An opportunity therefore exists to study post-traumatic pain without the confounding factors present in western societies.

Methods—In a prospective, controlled inception cohort study, 210 victims of a rear end collision were consecutively identified from the daily records of the Kaunas traffic police. Neck pain and headache were evaluated by mailed questionnaires shortly after the accident, after 2 months, and after 1 year. As controls, 210 sex and age matched subjects were randomly taken from the population register of the same geographical area and evaluated for the same symptoms immediately after their identification and after 1 year.

Results—Initial pain was reported by 47% of accident victims; 10% had neck pain alone, 18% had neck pain together with headache, and 19% had headache alone. The median duration of the initial neck pain was 3 days and maximal duration 17 days. The median duration of headache was 4.5 hours and the maximum duration was 20 days. After 1 year, there were no significant differences between the accident victims and the control group concerning frequency and intensity of these symptoms.

Conclusions—In a country were there is little awareness or experience among the general population of the notion that a whiplash injury may cause chronic pain and disability. Accident victims with acute symptoms from rear end collisions generally view this as a benign injury not requiring any medical attention. In a controlled historical cohort study of none of the 202 subjects involved in a car collision with rear end impact 1–3 years earlier had persistent or disabling complaints that could be conceivably linked to the accident. No significant differences between the accident victims and controls concerning prevalence of symptoms including neck pain, headache, and subjective cognitive dysfunction at the time of the interview were found. Thus we hypothesised that cultural and psychosocial factors may be important in explaining why accident victims in some other societies report chronic symptoms. Such factors may include expectation of disability, symptom amplification as a result of such expectation, and the effects of inappropriate therapy, insurance, and attribution of symptoms from non-accident related causes (spontaneous symptoms, occupational symptoms, symptoms before an accident being amplified after an accident).

The design of this earlier study did not allow for a precise and reliable estimation of the incidence, severity, and duration of initial symptoms. For such an analysis and to identify whether or not the Lithuanian accident victims actually develop an acute injury (which is a prerequisite for chronic disability), we performed a prospective controlled cohort study in Lithuanian citizens recently exposed to a rear end car collision.

Methods

STUDY GROUP
During 23 months we identified from the daily records of the Traffic Police Department of Kaunas, Lithuania, a consecutive group of 255 cars involved in rear end collisions. The records describe the circumstances of the accident and the vehicular damage. In this period there had been altogether 3616 traffic accidents that had led the traffic police to investigate the accident scene. All cars with description of a rear end damage were included in the present study.

A standard self report questionnaire was sent to the drivers between 2 and 7 days after the accident. They were asked about passengers in their cars, allowing an additional recruitment of accident victims who received the same questionnaire. All were asked about presence, frequency, and intensity of neck pain and headache before the accident. In addition they were asked about circumstances of the accident including confirmation and description of the accident; the subject’s position in the car; the
Figure 1  Distribution of duration of neck pain. * 24 hours or less.
subjects experienced pain shortly after the accident; 22 (10%) had neck pain alone, 37 (18%) had neck pain together with headache, and 39 (19%) had headache alone. Onset of neck pain was within 30 minutes in 37% of the cases, between 30 minutes and 24 hours in 44%, and between 1 and 3 days in 17%. There was only one subject in whom pain occurred between 4 and 7 days after the accident. In this case, neck pain lasted 4 days. The median duration of neck pain was 3 days (range <3 hours to 17 days). No subject reported severe or excruciating initial neck pain and only two reported severe initial headache. In no case did the neck pain persist beyond 17 days (fig 1). The median duration of headache was 4.5 hours and no one had accident induced headache beyond 20 days (fig 2).

The incidence of acute neck pain was 48% in those who reported neck pain ≥1 day/month before the accident and 25% in those with no or rare neck pain, before the accident (p<0.03). The incidence of acute headache was 64% in those reporting headache ≥1 day/month before the accident and 24% in those with no or rare neck pain before the accident (p<0.0001).

Sex, sitting position in the car, head position at the moment of the accident, use of seat belts, and presence and adjustment of the headrest did not influence the incidence of acute neck pain significantly (table 2). However, among the subjects in whom the headrest was adjusted with the upper border at or above the occiput no one experienced acute neck pain if the head had been placed on the headrest at the time of the collision.

Incidence of initial headache was 58% in women and 33% in men (p=0.01). The incidence of initial neck pain in those involved in high speed collision (41–95 km/hour) was 40% compared with 16% in those where collision speed was estimated to be below 21 km/hour ($\chi^2=6.7$, p<0.01). Thus despite probably highly inaccurate and often overestimated collision speed, a dose-response relation was found. In agreement, in occupants of cars with extensive damage, the incidence of initial pain was 52% compared with 10% for those in car accidents with minor damage ($\chi^2=17.2$, p<0.0001).

After 1 year, frequent neck pain (>7 days/month) was reported by 4.0% of accident victims (95% CI 1.9–8.1) compared with 6.2% of controls (95% CI 3.4–10.9) ($\chi^2=0.59$, p=0.44; table 3). Of the eight accident victims with frequent neck pain, the pain was described as mild by five and moderate by three. Three of them had had equally frequent neck pain before the accident. Three others did not report their pain in the second questionnaire after 2 months and did not relate it to the accident. The two others did not report long lasting or marked initial pain. Nor did they attribute their frequent neck pain to the accident. Of the 12 controls with frequent neck pain after 1 year, seven described their pain as mild, four as moderate, and one as severe. Eight of them did not have this neck pain when they completed the first questionnaire.

Neck mobility was after 1 year reported to be constantly reduced by 12% of accident victims and 18% of controls (p=0.09).

Frequent headache (>7 days/month) was reported by 5.1% of accident victims after 2 months compared with 6.2% of accident victims who reported having had frequent headache before the accident. After 1 year, frequent headache was reported by 4.0% of accident victims (95% CI 1.9–8.1) and 6.7% of controls (95% CI 3.8–11.5) ($\chi^2=0.96$, p=0.33). Headache occurring on ≥1 day/month was reported by 27.5% of accident victims and 33.2% of controls ($\chi^2=1.23$, p=0.27). Two accident victims and four controls had daily headache when interviewed after 1 year. Of the accident victims with frequent headache after 1 year, two described their pain as mild, five as moderate, and one as severe. Of the 13 controls with frequent headache after 1 year, four described their pain as mild, seven as moderate, one as severe, and one as excruciating. Six of them did not have this frequent headache when interviewed immediately after identification.

Our study had 80% post hoc power to detect a population difference in prevalence of neck pain. Table 2 shows the incidence of acute neck pain in relation to sex, position in the car, head position at the time of the accident, seat belt use and presence, and adjustment of headrest.
pain between groups ≥9% (16% in 200 accident victims vs 7% in 193 controls). If only the 98 subjects with acute pain were taken as the group at risk and compared with the remaining 295 subjects, the study still had 80% power to detect a 11% population difference. If the groups of our previous and present studies had been combined (797 subjects altogether), population differences of 6% (accident vs non-accident groups) and 7% (acute pain subjects vs pain free persons) respectively could have been detected.

Discussion
To our knowledge, this is the first prospective controlled inception cohort study of pain after whiplash. It confirms the findings of our earlier historical cohort study that rear end collisions do not seem to increase the risk of chronic pain. The setting was ideal for examining the natural history of acute whiplash injury because potentially intervening factors that could contribute to reporting chronic symptoms are largely absent in Lithuania.

To reduce expectation of symptoms to a minimum, we restricted our study to the use of mailed questionnaires. Any suggestion as to which persistent symptoms the car accident could lead to was avoided in the introductory letter and none of the accident victims was subjected to clinical investigations by us. Because only subjective symptoms were relevant, the last was also deemed unnecessary.

The questionnaire method is not wholly reliable, but any errors would be unbiased in controls and accident victims.

The results showed that just under half of an unselected cohort exposed to a significant whiplash mechanism due to a rear end car collision had acute pain. The symptoms were usually mild or moderate and disappeared in most cases after a few days. No subject reported accident induced pain later than 3 weeks. After 1 year, there were no significant differences between the accident victim group and the control group concerning frequency and intensity of both neck pain and headache.

Several previous studies have reported that symptoms persist after a neck injury in 15%-58% of accident victims.3,4 The power of our own two studies (the present study and Schrader et al), either analysed alone or combined, was sufficient to detect effects of less magnitude (6%-11%), even if only subjects who reported acute pain were selected for the group at risk.

Prevalence of neck pain and headache were of the same order of magnitude in both the accident victims and controls as found in western countries,10-12 confirming that our questionnaires were sensitive enough to find the symptoms in question. The results were also compatible with the notion that pain is experienced similarly by Lithuanians and by people in other cultures.

There is a remarkable agreement between the findings in our study and the findings reported in volunteer experiments with experimental collisions:

Firstly, despite being able to readily produce acute symptoms, thousands of experimental collisions have failed to produce a patient with chronic symptoms, regardless of the use of various vehicles, impact directions, and speeds, with or without headrest, with varying head positions, with or without tensed neck muscles, and more recently with both sexes and a wide range of young and old, and non-military volunteers.15-22 In these staged collisions of various types, the reported frequency of symptoms has been as high as 40%.17

Secondly, the duration of neck pain and headache in our study group agrees with that reported in the volunteers of the above quoted collisions. In those, headache has been reported to last for hours or days, with neck pain being reported in some cases lasting as long as 10 days.17

Thirdly, as in human volunteer collisions there was a positive relation between incidence of acute neck pain and the severity of collision in our study. Thus, despite probably highly inaccurate and often overestimated collision speed, a dose-response relation was found. This contrasts with claims of limited relevance of impact speed with respect to cervical spine impact.21-24

These similarities between the results of experimental collisions and the results in our study group confirm that Lithuanians are not different from subjects in western countries in response to injury.

It has been argued that persistent symptoms are more prevalent among women and passengers.25 As could be expected from an unselected cohort of car accident victims, the present sample included a majority of male drivers. This would significantly reduce the power to detect cases with late whiplash syndrome if males and car drivers never or seldom experience acute or sustained pain. To our knowledge, there is no study in which this has been shown. In a recent Norwegian study, 74% of those registered with neck sprain injuries from car collisions were drivers.9 In the same study, 41% of the injured persons were males and 59% females. At follow up after 2.5–8.5 years, 53% of these males and 62% of the females reported sustained symptoms which
they attributed to the accident—that is, there were only moderate sex differences.9

Presence and even correct position of the headrest did not reduce the incidence of acute pain. Our data suggest that placing the head on a correctly mounted headrest at the moment of the collision may prevent acute neck pain, a result that should serve as an incentive for implementation of headrest constructions that ensure continuous contact with the headrest while driving.

There was no significant difference in incidence of acute neck pain between those who had operating seat belts and those who had not, contrasting with the assumption that the increase of whiplash injuries is mainly due to the introduction of compulsory car seat belts.6

Rotated or inclined head position at the time of the impact has been assumed to be the primary feature related to the incidence of persisting symptoms.7 As no accident victim in our study continued to have accident related persistent pain we could only evaluate the incidence of acute pain related to head position. No such relation was found, however.

Sixty seven per cent of those in the control group who reported frequent neck pain (>7 days/month) in the interview after 1 year and 46% who reported frequent headache did not report this pain when interviewed for the first time. Hence, spontaneously occurring appreciable neck pain or headache during an observation period of 1 year is frequent also in untraumatized people and may erroneously have been attributed to the accident in studies in western countries.

In Lithuania a minority of car drivers are insured for personal injury, a factor that may have contributed to the divergence between our results and those of many previous studies. It remains difficult to estimate the importance of this contribution as long as numerous other confounding factors that are important in other societies24–26 are absent in Lithuania.

In summary, in a country where there is no expectation of symptoms or disability, and little involvement of the therapeutic community, acute pain after whiplash is, although frequent, mostly mild or moderate, short lasting, and self-limiting. The only identifiable significant risk factors seem to be neck pain or headache before the accident, and female sex for initial headache and impact severity. No case with evolution of chronic accident related pain was identified either in this prospective study of 210 subjects or in our earlier historical cohort study of 202 accident victims.

As almost all previous studies have been done in patients who have contacted the health service because of their injury, and thus may have been partly invalidated by selection bias, it remains to be shown whether the apparent discrepancy between our study and other studies is due to the absence of confounding factors in Lithuania or to the fact that a study with a controlled inception cohort design still has not been performed in western countries.

We thank Danpoulo Suriuiceni and Dalia Mickeviciene for their invaluable work with identification of accident victims and collection of data. The study was supported by grants from the Research Council of Norway and the Medical Faculty of the Norwegian University of Science and Technology.

Pain after whiplash: a prospective controlled inception cohort study
