Apolipoprotein E genotype related differences in brain lesions of multiple sclerosis

Franz Fazekas, Siegried Strasser-Fuchs, Helena Schmidt, Christian Enzinger, Stefan Ropele, Anita Lechner, Erich Flooh, Reinhold Schmidt; Hans-Peter Hartung

Abstract

Objectives—Clinical reports have speculated on a more severe course of multiple sclerosis in patients with the apolipoprotein E (apoE) e4 allele. As this could be reflected by differences in the severity of tissue damage MRI was used to obtain further support for a disease modifying effect of the apoE genotype.

Methods—Brain MR scans of 83 patients (mean age 35.5 (SD 9.5) years) who participated in a cross sectional study on the distribution of genotype patterns in multiple sclerosis. The total lesion load on proton density weighted (T2-LL) and T1 weighted scans (T1-LL) obtained with conventional spin echo sequences at 1.5 T was measured. A “black hole” ratio ((T1-LL/T2-LL)×100) was also calculated. This indicates the proportion of multiple sclerosis lesions with more severe tissue damage and may reflect disease aggressiveness or quality of repair.

Results—Patients with the apoE-e3/e4 genotype (n=19) showed a non-significantly greater T2-LL (16.0 (SD 14.0) cm³) than patients with the e2/e3 (n=11; 13.3 (9.5) cm³) or the e3/e3 genotype (n=49; 9.4 (SD 9.2) cm³). Both the T1-LL (2.6 (SD 3.3) v 1.6 (SD 2.4) and 1.2 (SD 3.0) cm³; p=0.04) and the black hole ratio (14.3 SD 11.9) v 7.4 (SD 9.3) and 8.4 (SD 13.3); p=0.02), however, were significantly higher in e3/e4 patients. Similar differences were seen when comparing patients with at least one e4 allele with the remainder of the group.

Conclusions—These data support speculations on a modulation of multiple sclerosis severity by the apoE genotype which can be attributed to more extensive tissue destruction or less efficient repair in carriers of the e4 allele.

Keywords: multiple sclerosis; apolipoprotein E genotype; magnetic resonance imaging

Multiple sclerosis is the most frequent neurological autoimmune disorder and the leading cause of serious neurological disability in early adulthood. Prevalence rates of multiple sclerosis vary substantially throughout the world and adulthood. Prevalence rates of multiple sclerosis but can also be attributed to more extensive tissue loss are seen on T1 weighted scans. These lesions have been termed “black holes” and the grade of MRI lesion hypointensity was shown to correspond well with the magnitude of axonal damage, extracellular oedema, and the degree of demyelination or remyelination.

Methods

Over a period of 5 months we obtained blood samples for apoE genotyping from all patients admitted to our multiple sclerosis outpatient clinic who met Poser’s criteria of laboratory supported or clinically definite multiple sclerosis. Eighty-nine of these 149 patients had undergone MRI at our institution. Six patients had to be excluded because of incomplete data or limited quality of the examinations. This left 83 patients (47 women, 36 men) with a mean (SD) age of 35.7 (9.5) years (range 17–60 years). Seventy-six patients had...
a relapsing-remitting course of multiple sclerosis, five were in the secondary progressive phase and two patients had primary progressive multiple sclerosis. After informed consent, all patients were examined by one neurologist (SS-F) who recorded the pertinent demographic data, duration, and course of the disease, disease severity according to the Kurtzke expanded disability status scale, and the number of relapses. Relapses were defined as new or worsening neurological signs or symptoms with a duration of more than 24 hours. Retrospective data were confirmed by a review of the patient’s charts.

All MRI examinations were performed on a 1.5 Tesla magnet (Philips Medical Systems, Eindhoven, The Netherlands)-test with a standard protocol using conventional spin echo sequences. This includes proton density and T2 weighted images (repetition time (TR)/echo time (TE): 2500 ms/30 and 90 ms) and T1 weighted images (TR/TE 600 ms/15 ms) in the axial plane. The T1 weighted sequence was performed after injection of gadolinium-DTPA in a dosage of 0.1 mmol/kg bodyweight. The slice thickness was 5 mm. The mean interval between MRI and the clinical examination at the time of blood sampling was 4.4 months.

Morphological analysis was performed on the PD weighted and T1 weighted images. Firstly, an experienced observer (FF) marked all lesions on hard copies. To improve reproducibility and concentrate on more marked tissue changes we used a stringent definition for black holes—that is, lesion hypointensity had to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF, or lower. All lesions on hard copies. To improve reproducibility and concentrate on more marked tissue changes we used a stringent definition for black holes—that is, lesion hypointensity had to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF or lower. Areas of mild hypointensity were treated to be at least between that of grey matter and CSF.

Using this technique, the intraobserver variability was 1.2% for measurements of the total volume of hyperintensities—that is, the T2 lesion load (T2-LL) and 4% for the entire “black hole” volume or T1 lesion load (T1-LL) in this study. This corresponds well with the intra-observer agreement reported by others. We also calculated a “black hole” ratio (BHR; (T1-LL/T2-LL) x 100) to indicate the proportion of more severe tissue destruction among multiple sclerosis lesions. All these analyses were performed without knowledge of the patients’ clinical condition or genotype.

ApoE genotyping was done according to the method of Hixon and Vernier after extraction of high molecular weight DNA from peripheral blood.

### STATISTICAL ANALYSIS

We used the statistical package for social sciences (SPSS/PC+) for data analysis. Categorical variables among the different apoE genotypes were compared by $\chi^2$ tests. We used Levene’s test to confirm a normal distribution of continuous variables. Comparisons of continuous variables between genotypes were conducted by Student’s $t$ test or with the non-parametric Mann-Whitney $U$ test in the absence of a normal distribution.

### Results

The apoE genotype frequencies were as follows: $e2/e2$ in two (2.4%), $e2/e3$ in 11 (13.3%), $e3/e3$ in 49 (59%) $e2/e4$ in one (1.2%), $e3/e4$ in 19 (22.9%), and $e4/e4$ in one (1.2%). This distribution of genotypes is in Hardy-Weinberg equilibrium. Consequently, the frequencies for the $e2$, $e3$, and $e4$ allele were 16, 128, and 22.

Demographic and clinical data for the total cohort and the $e2/e3$, $e3/e3$, and $e3/e4$ subsets at the time of blood sampling are shown in table 1. Patients with the $e3/e4$ genotype tended to be younger and had the highest mean EDSS score and number of relapses despite the shortest disease duration. A relapsing-remitting course was less frequent at examination in the presence of an $e3/e4$ genotype. However, none of these clinical differences reached significance.

The clinical data at the time of MRI showed a distribution of genotypes which was similar to that seen at the time of blood sampling. Results of the MRI analysis are shown in table 2.
Patients with the ε3/ε4 genotype had the greatest T2-LL. Differences in the T1-LL were even more pronounced and statistically significant between the ε3/ε4 and the ε3/ε3 genotype subgroups (p=0.018). Moreover, the black hole ratio was almost twice as high in patients with the ε3/ε4 genotype than in the other genotypes. Again this difference reached significance between ε3/ε4 and ε3/ε3 subsets (p=0.014).

Interestingly, active scans as indicated by the presence of contrast enhancing lesions were noted less often in ε3/ε4 patients, however (p=0.048). Comparison between carriers of at least one ε4 allele to the remainder of the study population confirmed a trend towards a higher T2-LL (15.1 (SD 13.7) v 10.4 (SD 9.2) cm³, p=0.24) and a significantly greater T1-LL (2.4 (SD 3.2) v 1.3 (SD 2.8) cm³, p=0.044) and black hole ratio (13.3 (SD 11.8) v 8.3 (SD 12.5)%, p=0.024) in ε4 patients (figure A–C).

Discussion

Earlier studies on the apoE genotype in multiple sclerosis have dealt primarily with allele frequencies and found no significant differences in the distribution of genotypes between patients with multiple sclerosis and the normal population. However, a more aggressive course of multiple sclerosis in patients with the apoE ε4 allele has been suggested by different investigators. This was not confirmed in a recent study on 361 patients with clinically definite multiple sclerosis. Morphological findings of the present study add to this controversy.

Using MRI in a cross sectional study design we found the highest lesion load in patients with multiple sclerosis with the apoE ε3/ε4 genotype. This difference was more pronounced for the T1-LL than the T2-LL and was significant between the ε3/ε4 and the ε3/ε3 subgroups. In parallel there was also a significant difference between these genotypes for the relative proportion of “black holes”. The black hole ratio of patients with the ε3/ε4 genotype was almost twice that of patients with an ε2/ε3 or ε3/ε3 genotype. Similar and significant differences were noted when comparing all patients with at least one ε4 allele to the remainder of the study population. Histopathological studies have shown that black holes represent multiple sclerosis lesions with more severe tissue destruction. Furthermore, using MR spectroscopy a direct correlation was found between the extent of hypointensity of multiple sclerosis lesions on T1-weighted images and the relative reduction in N-acetylaspartate, which is considered a marker for axonal density.

Therefore, our findings of a higher T1-LL and higher black hole ratio can be viewed as indirect evidence for a less favourable course of multiple sclerosis in patients carrying the ε4 allele. Clinically our patients with an apoE ε3/ε4 genotype also tended to have more aggressive disease with greater disability and a higher number of relapses experienced in a shorter period of time. These differences did not reach significance but are in line with the recent finding of a faster increase of disability in apoE ε4 carriers during 2 years of treatment with glatiramer acetate.

Whether a higher proportion of T1-LL in apoE ε4 patients is due to more aggressive disease with extensive demyelination or axonal loss within acute plaques or a consequence of less efficient repair thereafter cannot yet be determined. More active multiple sclerosis in apoE ε4 carriers could be another explanation for our findings. This was supported by their overall larger T2-LL and a somewhat higher number of relapses. However, a significantly lower frequency of active scans in patients with the apoE ε3/ε4 genotype argues against this assumption although this patient certainly suffers from the cross sectional design of our study and the relatively few patients examined. For these reasons and because the proportion of patients with any treatment was similar between genotype subgroups we also did not attempt to consider the possible influence of different treatments at the time of the MRI examination.

These preliminary results provide morphological support for a negative effect of the apoE ε4 allele on the course of multiple sclerosis. They also illustrate the capability of MRI to detect small differences between patient groups which clinically would have gone undetected. Although these data cannot serve to explain the reasons for divergent findings in previous clinical studies they indicate the need for further investigation of the role of the apoE genotype in multiple sclerosis. Such efforts may also take advantage of the sensitivity and objective nature of MRI findings in the future.
