Psychological impact of genetic testing for Huntington’s disease: an update of the literature

Bettina Meiser, Stewart Dunn

Abstract
Genetic testing has been available for Huntington’s disease for longer than any other adult onset genetic disorder. The discovery of the genetic mutation causing Huntington’s disease made possible the use of predictive testing to identify currently unaffected carriers. Concerns have been raised that predictive testing may lead to an increase in deaths by suicide among identified carriers, and these concerns set in motion research to assess the psychological impact of predictive testing for Huntington’s disease. This review article provides an overview of the literature and draws implications for clinical practice. About 10%–20% of people at risk request testing when approached by registries or testing centres. Most of the evidence suggests that non-carriers and carriers differ significantly in terms of short term, but not long term, general psychological distress. Adjustment to results was found to depend more on psychological adjustment before testing than the testing result itself. Although risk factors for psychological sequelae have been identified, few adverse events have been described and no obvious contraindications for testing people at risk have been identified. The psychological impact of testing may depend on whether testing was based on linkage analysis or mutation detection. Cohorts enrolled in mutation detection programmes have higher levels of depression before and after testing, compared with people who sought genetic testing when linkage analysis was available. There is evidence that people who choose to be tested are psychologically selected for a favourable response to testing. The impact of testing on people in settings where less intensive counselling protocols and eligibility criteria are used is unknown, and genetic testing is therefore best offered as part of comprehensive specialist counselling.

The frequency of Huntington’s disease in populations of European descent is between three and seven affected people per 100 000 population. The mean age of onset of Huntington’s disease is 40 years, with a mean duration of 15 years. About 98% of patients with Huntington’s disease have an expansion of a trinucleotide (CAG) repeat on the Huntington gene. No medical treatments to delay onset of disease or prophylactic strategies are available. The discovery of a genetic marker for Huntington’s disease in 1983 made possible the use of linkage analysis to identify currently unaffected carriers with a sensitivity of about 96%–99%. Linkage analysis takes advantage of the spatial proximity of a marker and a mutation and requires blood samples from both affected and unaffected family members over several generations. The nature of linkage analysis is probabilistic, because genetic recombination can occur between markers and the gene during meiosis. Most carriers and non-carriers were given risk estimates of 90% or more and 10% or less respectively, reflecting the relatively low accuracy of these earlier linkage studies. Since identification of the responsible gene mutation in 1993, direct mutation detection methods have been applied, leading to highly accurate predictive testing with a sensitivity and specificity of virtually 100%.

Compared with other dominantly inherited genetic traits leading to adult onset disorders, predictive testing for Huntington’s disease has been offered for the longest time. Carriers will definitely get the disease—that is, Huntington’s disease confers 100% penetrance, which refers to the proportion of carriers of a genetic alteration who will manifest the effects of it and is equivalent to lifetime incidence. Non-carriers definitely will not develop the disease.

When linkage analysis first became available, concerns were raised over the possibility of predictive testing leading to an increase in deaths by suicide among identified carriers. Suicide has long been recognised as a serious consequence of Huntington’s disease. One carefully designed study reports a fourfold increase in the suicide rate among people affected compared with the rate of the general white population in the United States. Attitudinal surveys of people at risk suggest that between 11% and 33% considered suicide a
possible response in the future.\textsuperscript{6} These data highlighted the need for research to identify predictors of depression and suicidal intention in people entering predictive testing programmes for Huntington’s disease. The identification of the genetic marker prompted a considerable amount of research on attitudes to, and the psychological impact of, testing for the disease.

### Attitudes to genetic testing for Huntington’s disease

Methodological aspects and major findings of intention to test surveys of people at risk carried out since the genetic marker was identified, but before mutation analysis became available, are summarised in table 1.

Between 40% and 79% of people at risk of developing Huntington’s disease reported intention to use the test. Interest in genetic testing was found to be negatively associated with being married, and positively correlated with the number of affected relatives and earlier parental age of onset of Huntington’s disease.\textsuperscript{6} The most commonly reported reasons for wanting to be tested were: to be certain, to plan for the future, and to inform children.\textsuperscript{15}

Data on actual uptake of testing suggest that uptake has been much lower than suggested by attitudinal surveys. The percentage of people at risk who requested testing when approached by registries or testing centres varied from 9\% in Wales, 10\% in Indiana, 16\% in the Manchester area, to 20\% in the Vancouver area.\textsuperscript{11} On the basis of the relatively low rate of uptake, it is likely that people who chose to be tested are not representative of the Huntington’s disease population as a whole.\textsuperscript{15}

People who decide to have the test are more likely to have higher educational levels than the general population, and women tend to be overrepresented,\textsuperscript{17} possibly reflecting women’s traditionally greater involvement in reproductive decisions or concern for existing children.\textsuperscript{17}

### Self selection for favourable psychological response

Several studies have provided evidence that people who choose to be tested are psychologically selected for a favourable response to testing. People who reported being at risk of suicide or anticipated feeling depressed should the result be positive were significantly less likely to want the test, compared with those not anticipating suicidal or depressive feelings.\textsuperscript{6,8} The most commonly reported reasons for choosing not to have the test related to the emotional and psychological consequences of a positive test result—such as fear of searching for symptoms and of losing what hope could be retained.\textsuperscript{18} Other reasons for choosing not to test were: increased risk to children if found to be a carrier, absence of an effective cure, and potential loss of health insurance.\textsuperscript{18}

Compared with test recipients, people who declined testing were found to be significantly more depressed and pessimistic.\textsuperscript{19} They were more likely to expect to be carriers and anticipated more negative effects from a positive result.\textsuperscript{18} Interestingly, people who declined were more likely to have learned about their being at risk for Huntington’s disease during adolescence, rather than adulthood.\textsuperscript{18}

Studies that compared psychological characteristics of people who had enrolled in a linkage testing programme with those of the general population found that psychological adjustment was comparable.\textsuperscript{17} However, people at risk were found to be more resourceful than the general population.\textsuperscript{17} Mean anxiety and depression scores were found to be lower than means for the general population, and test applicants had significantly higher ego strength and were more socially extroverted.\textsuperscript{15}

The evidence on self selection for a favourable response of people who choose to have the test suggests that findings of studies on the psychological impact of genetic testing for Huntington’s disease may not be generalisable to the population of people at risk of Huntington’s disease at large. It has been suggested that those who are best equipped emotionally to deal with the information opt for genetic testing.\textsuperscript{21} Alternatively, it is possible that those who are psychologically more vulnerable do not follow through the typically rigorous counselling and testing protocols.

Generalisability to settings where less intensive counselling protocols and eligibility criteria are used is also limited, given that all psychological impact studies reviewed were conducted as part of carefully designed research programmes with comprehensive counselling.\textsuperscript{4} People with less ego strength might have experienced considerable psychological support through these often extensive programmes of counselling before and after testing.

### Differences in impact of testing between linkage analysis and mutation detection

There is evidence that cohorts enrolled in direct testing protocols since 1993 have higher levels of depression before testing, compared with people who sought genetic

testing when linkage analysis was available. The psychological impact of testing may depend on whether testing was based on linkage analysis or mutation detection. Published studies include people tested by linkage, or mutation detection, or a combination of both. Only one study permits a comparison of the impact of different testing strategies. People tested by mutation detection had higher depression scores 12 months after disclosure compared with those tested by linkage. Several reasons for the differences in psychological adjustment between the cohorts have been suggested. People who present for linkage testing may have had greater social support before testing than those who do not have “to orchestrate a family-wide effort to collect the blood samples required for Huntington’s disease linkage testing”. Alternatively, the need to call on other family members for participation in linkage testing might lead to improved family communication and hence support. Finally, the risk information presented during genetic counselling within the context of linkage testing may account for the effect. Carriers may have been consoled by knowing that there is a 1% chance that they are not carriers; thereby providing increased scope for optimism bias and its protective effects on mental health.

**Psychological impact of genetic testing for Huntington’s disease**

Table 2 presents a summary of methodological aspects and major findings of prospective studies that used standardised measures of psychological outcome and evaluated the psychological impact of genetic testing for Huntington’s disease. The table indicates which studies were based on linkage and which on mutation analysis and presents results of significance tests between carriers and non-carriers 7–10 days and 12 months after disclosure. For ease of comprehension, people who underwent linkage analysis and received increased risk results will be referred to as carriers and those with decreased risk results as non-carriers. Carriers and non-carriers differed significantly on all psychological outcomes at the 7–10 days, but not the 6 months and 12 months of follow up. However, the study based on the largest sample size to date measured hopelessness as a dimension of particular relevance to the population of people at risk and found that differences between carriers and non-carriers may persist long term. This finding raises some concern about this particular population, given that hopelessness has been identified as a predictor of suicide.

The analysis of scores before, compared with after, receiving the test result (results not shown in table 2) indicates that psychological adjustment of non-carriers either tends to be unaltered or improves after receipt of the result. Some studies found no significant changes from baseline on any follow up measures for carriers, whereas others found short term increases in hopelessness.

One study used a control group design and showed that people at risk who did not receive a genetic testing result had higher scores for depression and lower scores for wellbeing at the 12 month follow up, compared with both carriers and non-carriers. The authors conclude that receiving a test result leads to psychological benefits, even if it indicates carrier status, by reducing uncertainty and providing an opportunity for appropriate planning.

Baseline levels of depression or hopelessness (rather than the test result itself) were found to be the best predictors of levels of hopelessness and intrusive thoughts after disclosure. People who were married, had no children, and were closer to their estimated ages of onset of Huntington’s disease were found to be less well adjusted at all times.

An unexpected finding was that a small proportion of non-carriers who received a low risk result experienced serious difficulties in coping with their new genetic status. In depth interviews showed that having made irreversible decisions based on the belief that they would develop Huntington’s disease or overly optimistic expectations of the positive effects of a decreased risk were contributing factors. Survivor guilt—that is, guilt feelings relative to other family members who tested positive or those with unaltered non-carrier scores at each time point.

already affected by Huntington's disease, were also found.31

IMPACT ON PARTNERS OF PEOPLE UNDERGOING GENETIC TESTING

Tibben et al also followed up partners of people undergoing genetic testing, and found that car-
riers' partners showed the same course of distress as carriers.32 Compared with non-
carriers' partners, carriers' partners had significantly higher levels of psychological distress 1
week, 6 months, and 3 years after disclosure.32 Having children was an additional psychological
risk factor for carriers' partners, who showed significantly higher scores on all psychological outcome measures both short and long term, compared with carriers' partners
without children.32 These findings are similar to those of Quaid and Wesson and indicate that
genetic testing for Huntington's disease has significant effects on partners of carriers, suggesting the need to include partners more comprehensively in psychological assessments.33

Conclusion

Most of the evidence on the psychological impact of testing for Huntington's disease suggests that non-carriers and carriers differ significantly in short term, but not long term, general psychological distress. Carriers show either no changes from psychological adjust-
ment before testing24 27 or only short term increases in hopelessness.28 Adjustment to results was found to depend more on psycho-
logical adjustment before testing than the testing
result itself.24 27 32 Although risk factors have been identified,33 few adverse events have been described,16 38 and no obvious contraindications for testing have been identified.39 The impact of testing on people in settings where less intensive counselling proto-
cols and eligibility criteria are used is unknown, and genetic testing is therefore best
offered as part of comprehensive specialist counselling. There is evidence that people who
choose to be tested are psychologically se-
lected for a favourable response to testing. Given the potential psychological sequelae of
genetic testing in less well adjusted people, it is advisable to routinely assess levels of depres-
ion or hopelessness with formal assessment
tools.22 People with high levels of depression or hopelessness may benefit from referral to liai-
sion staff with expertise in psychiatry or clinical psychology before decision making about
genetic testing.

HENRY HEAD (1861–1940)

Henry Head was born of Quaker stock on 4 August 1861 at 6 Park Road, Stoke Newington, son of an insurance broker at Lloyds. Educated at Charterhouse and Trinity College, Cambridge (1st class in both parts of the Natural Science Tripos), he chose to study Medicine, influenced by his mother’s cousin, Marcus Beck, who had been Joseph Lister’s assistant. For a period after Cambridge, he worked with Hering on respiratory physiology in Prague, acquiring fluency in both French and German. Head returned to University College Hospital, qualifying in 1890. He worked at Queen Square under Thomas Buzzard, and at Victoria Park Hospital for Chest Diseases, where he developed his interests in pain and in physiology. His Cambridge MD thesis, On disturbances of sensation with special reference to the pain of visceral disease, was later published in Brain (1893). It was of outstanding merit.

He was registrar, then assistant physician at the London Hospital, where his gifts as a born teacher, impelled to impart information, brought crowds of admiring students from afar. “Henry Head doing gait was a perennial sight,” said Sherren and Rivers, he made many observations on himself after sectioning the superficial rami of his own radial nerve. He undertook this experiment because of his annoyance with the notion of what he scornfully described as the “diagram-makers.” Describing “semanitic aphasia,” he provided a link between the linguistic and the intellectual aspects of speech. The full implications of this work have been credited and amplified by modern aphasiologists. His later works related to the concepts of attention and vigilance, and the idea of body image. These, and Head’s notions of dynamic schemas in thought processes, which were manifest as symbolic formulation and expression, were well in advance of his time.

His writings include a volume of attractive verse, The destroyers. He was the author of Allbutt’s System of Medicine, and he edited Brain from 1910 to 1925.

After his study on cutaneous sensation and dermatomes, Head’s investigations were devoted mainly to the sensory system, where his original thought and skilled clinical techniques brought order out of chaos. He postulated that the different susceptibilities of sensation was, however, severely criticised. Recent recording from single sensory neurons has partly reaffirmed Head’s separation of highly differentiated sensations from other types. He did indeed provide the first rational explanation of the nature of sensory dissociation. The clinical facts and techniques, which he and his collaborators established, remain the basis for many clinical investigations of sensation today.

His extensive study of spinal reflex functions also illuminated and provoked interest in this relatively neglected area. It arose in the first world war, when he worked with George Riddoch on war injuries. They studied spinal cord injury and paraplegia yielding important papers, and knowledge that would save many such future casualties.

Brain disorders were likewise the subject of his inquiring mind. He wrote an important paper with Gordon Holmes in 1911 on sensory disturbances from cerebral lesions. His last major work, Aphasia and kindred disorders of speech, appeared in two volumes in 1926, lauded by Critchley as “the finest monograph on the subject of aphasia in the neurological literature.” Here, his originality brought critical definition to the then materialistic notions of what he scornfully described as the “diagram-makers.” Describing “semantic aphasia,” he provided a link between the linguistic and the intellectual aspects of speech. The full implications of this work have been credited and amplified by modern aphasiologists. His later works related to the concepts of attention and vigilance, and the idea of body image. These, and Head’s notions of dynamic schemas in thought processes, which were manifest as symbolic formulation and expression, were well in advance of his time.
