Head drop and camptocormia
T Umapathi, V Chaudhry, D Cornblath, D Drachman, J Griffin, R Kuncl

The spectrum of bent spine disorders

Head drop (drop) results from weakness of the neck extensor, or increased tone of the flexor muscles. It is characterised by marked anterior curvature or angulation of the cervical spine and is associated with various neuromuscular (table 1) and extrapyramidal disorders.1-5 Camptocormia or the bent spine syndrome was first described in hysterical soldiers in 1915 by the French neurologist Souques.6 Typically there is marked anterior curvature of the thoracolumbar spine. In some patients the spine is angulated forward, the arms propped against the thigh for support. More cases, all among soldiers, were reported during the first and second world wars. These patients responded well to psychotherapy. Recently camptocormia arising as a result of weakness or abnormality in the tone of the paraspinal muscles has been described (table 2). In contrast with other skeletal disorders of the spine such as kyphosis, the deformity in head ptosis and camptocormia is not fixed and is corrected by passive extension or lying in the supine position. It is not possible to straighten the neck or back voluntarily. The evaluation of these disorders can indeed be challenging and often no definite diagnosis is made, as illustrated by four cases of head ptosis and camptocormia seen by us at the Johns Hopkins Hospital.

CASE A
An 80 year old man developed head ptosis insidiously over a period of few weeks. A week before this he had an upper respiratory tract infection and also experienced transient sharp pain over the left and then the right shoulder. He had no diplopia, dysarthria, dysphagia, limb weakness, or fatiguability. Examination showed severe neck extensor weakness, Medical Research Council (MRC) grade 2. Muscle strength was normal in all other cranial, proximal, and distal limb muscles. Serum creatine kinase (CK) was 362 IU/l (normal 24–195) at presentation. Anti-acetylcholine receptor antibody was not detected. Repetitive nerve stimulation of right biceps, right nasalis and right trapezius was normal. A therapeutic trial of pyridostigmine failed. Cervical spine MRI did not show significant compression of the cord, roots, or any specific changes in the paraspinal muscles. An EMG disclosed positive sharp waves restricted to lower cervical paraspinal muscles. To reduce confounding from neuropathic changes secondary to coexistent age related spondylotic changes, the thoracic paraspinal muscle was chosen for biopsy. The pathological findings were mixed. There were neuropathic changes such as angular atrophic fibres; occasional nuclear sacs, target and targetoid fibres as well as myopathic features such as the presence of hypertrophic and split muscle fibres; a few necrotic, degenerating and regenerating fibres; increased internalised nuclei, and mild endomyssial fibrosis. No type grouping was noted, but there was massive type I predominance. No specific treatment was offered. A few months later, he started to improve. At follow up 2 years later, he was able to keep his head up for prolonged periods, especially in the sitting position. However, he was more symptomatic while standing. He reported an overall 60% subjective improvement in neck strength and weakness had not progressed to other muscles.

CASE B
A 74 year old man with diabetes mellitus and hyperlipidaemia (for which he had been taking a statin for a few years) complained of progressive anterior curvature of the spine associated with proximal limb weakness for few months. On examination, he had moderately severe anterior thoracolumbar curvature that could be extended passively. Diffuse weakness was present; proximal limb strength was MRC grade 4 and distal, 4+. Electrodiagnostic evaluation only showed evidence of an axonal polyneuropathy, consistent with diabetes. Serum CK was persistently raised (367 IU/l). Spine MRI only showed mild degenerative changes. Anti-acetylcholine receptor antibody was not detected. Biopsy of the rectus femoris showed increased fibre size variability, necrosis, mild fibrosis, occasional red rimmed vacuoles, and one fibre which stained positive for ubiquitin, suggestive of inclusion body myositis. However, inflammation or amyloid

Abbreviations: CK, creatine kinase; MSA, multisystem atrophy; ALS, amyotrophic lateral sclerosis
deposition were not seen. Despite stopping statin, his weakness continues to progress and CK has remained raised (239 IU/L).

CASE C
A 59 year old woman presented with a 4 year history of progressive, painless anterior curvature of the spine. She had a family history of facioscapulohumeral muscular dystrophy but not of bent spine. Examination showed camptocormia along with scapular wings and mild facial and proximal weakness. Her CK was at the upper limit of normal, 186 IU/L. An EMG showed short duration, small amplitude motor units with early recruitment in the proximal muscles. Abnormal spontaneous activity was seen in the thoracic paraspinal muscles. No decremental response to repetitive nerve stimulation was present. Spine MRI was unremarkable. 4q35 gene deletion, consistent with facioscapulohumeral muscular dystrophy, was detected.

CASE D
A 63 year old woman developed slowly progressive... painless... scapular... scapulocoronal... scapula... scapulocoronal... scapulocoronal... scapulocoronal... scapulocoronal...

Yoshiyama et al 27 published a series of seven patients with parkinsonism exhibiting head drop, four of whom carried a diagnosis of probable MSA. Although at rest there was no anterior neck spasm, attempts to extend the head voluntarily or passively were resisted by contraction of the sternocleidomastoid muscles on surface EMG in all of these patients. There was no correlation between the severity of the head ptosis and parkinsonism. Three patients had improvement of neck symptoms with treatment of parkinsonism, whereas one worsened. A recent report described head ptosis in seven out of 459 patients worsened. A recent report described head ptosis in seven out of 459 patients. The abnormality developed in two patients. In all the cases examined, there was no anterior neck spasm, although deep muscles may be involved. Speech, swallowing, and upgaze deficits are often associated. Trials of botulinum toxin into both sternocleidomastoid muscles are ineffective and response to levodopa generally disappointing. 11,21 Earlier case reports have also documented the association between MSA and head drop. 27

EDIOPATHIC HEAD DROP
In some cases, no obvious aetiology for the head drop is apparent even after extensive evaluation and on prolonged follow up.11-13 Combining the data from various reports of idiopathic head ptosis in the literature and patients seen at our institution (table 3), the following profile of idiopathic head ptosis emerges. The female to male ratio is 3:2. Mean and median ages at presentation are 74.5 and 73 respectively. The onset is often subacute, over days and weeks rather than months. Two of our patients and one that was reported by Lerman11 had a history of significant weight loss. Discomfort at the back of the neck is reported in some patients but other sensory abnormalities are not prominent. The weakness is profound in the neck extensors, and involvement of contiguous proximal muscles is at most modest. The CK was normal in all but two patients. Katz et al 14 reported oedema-like changes and atrophy of the neck extensor muscles on MRI. An EMG of the paraspinal muscles was remarkable for the increased reports of spontaneous activity. Fibrillations were present in nine and positive sharp waves in one out of the 15 patients for whom EMG data are available. Interestingly, such abnormalities were pronounced in the lower cervical segments; and in one case reported by Katz et al,27 extended to the midthoracic region. The motor unit action potentials in most cases are described as having short duration and small amplitude with early recruitment. However, this has to be interpreted with caution as paraspinal motor unit action potentials are generally small and may have multiple turns even in normal individuals. EMG of the limb muscles is mostly unremarkable. The histology of limb muscles is normal or reveals mild non-specific myopathic changes such as increased fibre size variability. In two of our cases there is some evidence of denervation. The paraspinal muscle biopsies show less subtle but again non-specific changes such as fibrosis, increased fibre size variability, “moth eaten” fibres, and myofibrillar disarray. Degeneration, regeneration, and necrosis were reported by Jaster et al 15 and also seen in one of our patients. Interestingly, as mentioned above, similar biopsy findings have been reported in the neck extensor muscles of patients with parkinsonism who also have head drop,15 suggesting that these changes may not be specific for a neuro muscular disorder.

The weakness remains localised and in most cases stabilises after a short period of progression. In some patients (including our case A) there is some documented recovery. Secondary skeletal deformity can result in disability even after good recovery of neck strength,16 highlighting the importance of maintaining good neck posture during the period of weakness. Immunosuppressive agents have been tried for varying periods with disappointing results overall. Rose et al 17 reported a positive effect with prolonged corticosteroids, but their patient had generalised weakness and inflammatory infiltrates (albeit scanty) in one biopsy. There may be a role for cervical spine fusion in allowing patients with disabling and non recovering head drop to maintain a functionally useful head position.

Camptocormia
The causes of camptocormia are summarised in table 2. As in head drop, several

neuromuscular diseases can present with segmental involvement of the postural muscles, resulting in camptocormia.

Amyotrophic lateral sclerosis (ALS)
The kyphoscoliotic posture along with head drop is typical in patients with moderately advanced ALS. Involvement of paraspinal muscles was described by Gower in his account of patients with ALS. In most cases, the wasting involves the muscles of the back, and it sometimes begins in them. Our group had previously reported a patient with ALS who developed severe camptocormia, requiring him to support himself with his thighs. Limb muscles were less involved in this patient.

Myopathy
Most generalised myopathies, because of pelvic girdle weakness, cause lumbar lordosis rather than kyphosis. The exception may be inclusion body myositis (IBM). This was reported as a cause of rector spine weakness by Hund et al. A 70 year old man developed back and later leg weakness over a period of months. The CK was slightly raised. An MRI. The EMGs of the paraspinal muscles done in five patients were normal. Three patients apparently had immediate and reversible aggravation of the bent spine with levodopa therapy whereas the others improved. The authors postulated that camptocormia in Parkinson's disease may represent a type of dystonia.

Postencephalitic parkinsonism has also been reported to cause curvature of the spine. Onuaguluchi reported five cases in 1964, followed a year later by a series consisting of 14 cases from Martin. The latter included seven photo illustrated case histories. The spinal curvature in these patients was in both anterior-posterior as well as lateral planes and diminished in the supine position. In many patients it was noted to extend "from sacrum to neck". In one woman the forward flexion of the neck was only seen when she was blindfolded. There was no consistent relation of the spinal curvature to the side of greater muscular rigidity. Three patients underwent stereotactic surgery. One patient received lesions to the ventrolateral thalamus and pallidium and another to the pallidium alone, ipsilateral to the concavity of the spine. A third patient received a lesion to the pallidium contralateral to the side of spinal curvature. In all the cases rigidity and tremor on the opposite side was abolished; but the spinal curvature was corrected only in the cases where the stereotactic lesion was placed ipsilateral to the concavity of the spinal curvature. Animal work by Ferrier, Des-Massel and Hassen had previously shown that unilateral caudate lesions could cause a similar deformity of the spine in animals, which can be corrected by destruction of the contra-lateral head of the caudate nucleus. Severe pathological changes have been described in the caudate nucleus in postencephalitic parkinsonism. Martin hypothesised that tonic activity in the caudate nucleus and its efferent pathways to the pallidium might play an important part in maintaining spinal posture. The slowly progressive and chronic forms of a rare encephalomyelitis that occurs among the Lakat people of Siberia, termed Vilitsuk encephalomyelitis, is also characterised by a forward bent posture. Other features include rigidity, bradykinesia, dementia, and dysarthria. Pathological findings include multiple areas of inflammation, necrosis, perivascular leucocytic cuffing, spongiform changes, and fibrosis as well as marked atrophy of the basal ganglia. Camptocormia was reported as a side effect of sodium valproate toxicity in a 23 year old epileptic patient. Interestingly the deformity resolved when the plasma valproate level dropped to about 300 µmol/l, only to return 4 months later when the plasma concentration rose to about 330–530 µmol/l. This patient had no other extrapyramidal features. Reversible parkinsonism has been well documented as a rare side effect of valproate and an extrapyramidal mechanism might have been responsible for the effect of valproate on spinal posture.

IDIOPATHIC CAMPTOCORMIA
In some cases of camptocormia, such as postpolio, the clinical abnormality remains confined to the back and no apparent cause is found even on protracted follow up. Is idiopathic camptocormia a distinct entity? Table 4 summarises the various reports on this condition. The data from these studies were combined with our cases B and D to develop a profile of idiopathic camptocormia. The incidence of camptocormia, like head drop, increases with advancing age. All but eight patients developed it at an age older than 60. The earliest age of onset is 49 years. The male to female ratio is about 3:1. The weakness is mainly confined to the extensor muscles of the spine. Onset and progression are more chronic compared with head drop, often extending over a period of months to years. Mild back discomfort was present in a few. Sensory symptoms were absent. The presence of a family history in some patients suggests that investigations for genetic and congenital neuromuscular conditions such as facioscapulohumeral muscular dystrophy and nemaline myopathy may result in better characterisation of the idiopathic cases. The CK is raised in cases B and D and in some of the cases described by Hilliquin et al and Serratrice et al. The paraspinal muscles have been reported to show atrophy and a heterogeneous appearance on radiological examination (CT or MRI). The EMG findings are not uniform, with reports of both myogenic and neurogenic features. In case D, spontaneous activity consisting of positive sharp waves, fibrillation potentials, and complex repetitive discharges is seen only in the right lower cervical paraspinal muscles, probably an incidental finding.

The pathological abnormalities were more common and severe with

Ehrenstein reported complex repetitive discharges in the lumbar paraspinal and limb muscles in his single case report. The paraspinal muscle biopsy findings are generally myopathic with increased fibrosis, variation in fibre size, and atrophy. Limb muscle histology is variable and no definite pattern was discernible. Cases B and D had necrotic muscle fibres, and the former rimmed vacuoles, but no specific diagnosis could be made. Information on therapeutic options is sparse and difficult to interpret. Some authors have reported dramatic recovery with intravenous methylprednisolone. The early use of corsets and other forms of spinal support may be useful to prevent the formation of fixed secondary deformaties.

Idiopathic head ptosis and camptocormia: possible pathophysiological factors

Head ptosis and camptocormia are age related disorders

Idiopathic head ptosis and camptocormia occur mainly in those beyond the age of 60 and are almost never seen at ages less than 50 years. It seems that the age at presentation of head ptosis and camptocormia is advanced even in patients with an underlying disorder. In a recent study of 10 elderly patients with myasthenia gravis, age range 80-88 years, head drop was the commonest presentation, occurring in six patients. By contrast, ptosis was the presenting complaint in only three patients. Nemateline myopathy in childhood is associated with spinal abnormalities such as rigidity, scoliosis, and lumbar lordosis. However, in adult onset cases camptocormia and a high incidence of head ptosis have been reported.

Katz et al have proposed that in elderly people, age related loss of tissue elasticity and mild kyphosis predisposes to chronic stretch injury of paraspinal muscles and may contribute to the development of head ptosis. Similar factors may be involved in the pathogenesis of idiopathic camptocormia. As discussed above, some of the reported histological changes in the paraspinal muscles of patients with idiopathic head ptosis were also seen in those with an obvious extrapyramidal cause, suggesting that these changes may be non-specific changes, resulting from chronic mechanical strain rather than a specific myopathic disorder. Furthermore, in a study comparing the cervical paraspinal muscle morphology in patients with cervical myelopathies and normal necropy controls, necrosis, core, targetoid changes, type II atrophy, and type I predominance were seen in both groups with similar prevalence and severity. The pathological abnormalities were more common and severe with

www.jnnp.com
increasing age of patients in disease and control biopsies.\textsuperscript{51, 52} Hence, it may be difficult to make a specific aetiologic diagnosis by studying the paraspinal muscles alone.

Probable neuropathic contribution to the pathophysiology of idiopathic head drop and camptocormia

Pennison-Besnier \textit{et al}\textsuperscript{45} described a 72 year old woman with a 16 month history of camptocormia, whose lumbar paravertebral muscle showed fibrosis, fatty infiltration of interfascicular septa, groups of angular atrophic fibres, nuclear bags, fibre type grouping on ATPase stain, core, and target fibres. They think that denervation of the paraspinal muscles from impingement of the dorsal rami by osteoarthritic facet joints causes camptocormia. They asserted that the paraspinal muscle biopsies of other reports and two of their patients might not have shown typical neurogenic changes because they were performed late in the course of the illness. However, as already mentioned, neurogenic changes on muscle biopsy are common in elderly people and may not be clinically significant.\textsuperscript{51, 52} This is especially true in the cervical and lumbar paraspinal muscles, where there is a high incidence of degenerative vertebral disease in elderly people. Furthermore, to cause significant weakness of spinal extension large segments of the paraspinal muscles need to be denervated as sectioning of C1-C6 dorsal branches in patients with spasmodic torticollis\textsuperscript{53} does not cause any functional impairment. In addition, although spondylodiscitis could conceivably damage neural elements by vascular compromise, either from arterial ischaemia at the watershed region of the spinal arteries of Adamkiewicz or venous congestion, direct impingement of spinal roots have not been reported in patients with idiopathic head ptosis and camptocormia (tables 3 and 4). Therefore it is more likely that chronic denervation of the paraspinal muscles is a contributing factor rather than the basis for the development of idiopathic head ptosis and camptocormia.

The presence of pain, relatively acute onset, and recovery of head drop over a period of weeks in some patients is reminiscent of the clinical course of brachial neuritis (Parsonage-Turner syndrome). Indeed the clinical diversity of this condition has been well documented,\textsuperscript{45, 54} including involvement of structures as proximal as the roots. Kidron \textit{et al}\textsuperscript{45} had reported C6 root involvement with paraspinal denervation.\textsuperscript{45} Whether a similar process can selectively involve the cervical plexus and the dorsal spinal nerves can only be confirmed by studying the histology of paraspinal muscles and dorsal spinal nerves early in the course of the illness.

\caption{Similarities and differences between head ptosis and camptocormia}
\end{table}

\textbf{HEAD PTOSIS AND CAMPTOCORMIA: PARTS OF A SPECTRUM?}

In most instances head drop and camptocormia are not related. It is rare to find a patient with both disorders except in extrapyramidal disorders such as MSA and postencephalitic parkinsonism.\textsuperscript{21} However, the similarities between them (table 5) suggest that both head ptosis and camptocormia may occur as a result of similar pathophysiological processes affecting paraspinal muscles of different parts of the spine. In any individual patient local factors such as chronic denervation and loss of tissue elasticity may determine the spinal segment involved.

In summary, head ptosis and camptocormia include a diverse group of disorders that share in common involvement of different parts of the spine resulting in disabling anterior curvature of the spine. In addition to the known causes of flexion deformity of the spine, such as myasthenia gravis, amyotrophic lateral sclerosis, and Parkinson's disease, multiple cumulative age related factors such as loss of muscle tone, tissue elasticity, chronic stretch and denervation of the paraspinal muscles from degenerative spinal disease, may be involved in the pathogenesis. In practice, neuromuscular and extrapyramidal disorders, because of therapeutic and prognostic implications, should be ruled out in all patients. Measures to prevent fixed deformities—for example, passive mobilisation of the spine and the use of supports such as corsets and stiff collars—should be instituted early. At least some patients with idiopathic head drop recover partial function spontaneously. There is no clearly defined role for immunosuppressive or other pharmacotherapy. The case report of valproate induced reversible camptocormia introduces the intriguing possibility of using a GABA agonist in cases with an apparent extrapyramidal aetiology. Patients whose head ptosis does not improve should be considered for cervical fusion, which allows the patient to maintain a functionally useful head position.

\textbf{ACKNOWLEDGEMENTS}

We thank Dr R Kurtzke, Fairfax, Virginia for providing us with information on his patient and valuable comments, and Dr M P T Lunn, Guy's, St Thomas', and King's School of Medicine, London, for contributing important ideas.

Measuring carotid stenosis

Compared with a new test with a standard involves measuring disagreement. In the case of measuring carotid artery stenosis, some of the disagreement between different tests is because of inherent differences in how the stenosis is demonstrated (test characteristics). This is what we are most interested in when assessing a new technology. However, some of the disagreement simply reflects variability in how we physically make the measurement with the standard technique. Choosing the point of maximum stenosis, choosing the point in the common carotid artery for use as a denominator, measuring from an eyepiece, or measuring from calipers all introduce variation when measuring carotid stenosis. The resulting observer variabilities in reporting contributes to disagreement between methods but to some extent is independent of the method used to generate the angiogram in the first place.

In the medical literature, disagreement between methods is often attributed entirely to test characteristics, with little appreciation of the role of observer variability in reporting. When one method is compared with another all agreements emerge, it is not readily apparent how much of the disagreement is caused by the method used and how much by the process of measurement, unless observer variability data are presented. We also presented the recent paper from Patel et al., interobserver variability data are presented but their significance in relation to overall disagreement does not appear to have been appreciated.

Using the data from Patel et al. (Tables 2 and 4) for symptomatic carotid arteries, it is noted that when 34 carotid digital subtraction angiograms (DSA) are measured by one radiologist, there was disagreement in seven cases when the same films were reported by a second radiologist. If only DSA was used, seven patients would have had “inappropriate” surgery according to which radiologist read the angiogram. This is not surprising, and such disagreement is a consistent finding in observer variability studies.1 2 Observer variability in reporting DSA therefore accounted for approximately 20% of disagreement in this particular series of angiograms. This sets a limit on the maximum agreement that any alternative method can demonstrate when compared with DSA. It is clearly not reasonable to expect better agreement from another method than can be obtained by re-reporting the DSA films themselves. In Patel’s table 2, when the same arteries are assessed by computed tomographic angiography (CTA) and ultrasound there was disagreement with DSA in seven cases, while with magnetic resonance angiography (MRA) and ultrasound there was disagreement in six and seven cases, respectively. The three alternative methods disagree with DSA to the same extent as can be attributed to observer disagreement in reporting DSA. Put simply, the same number of missed or unnecessary operations would have occurred (roughly 20% in this series) whatever method was used, including DSA alone. Observer variability is not confined to DSA, and the scatter plots from Patel et al. (Fig 2) would suggest—in keeping with other studies—that observer variability is greater for MRA and CTA than for DSA.3 It is surprising that this did not translate into clinically important disagreements when MRA and CTA were compared with DSA. This is probably accounted for by the fact that in this study, for MRA and CTA, consensus views were taken for any disagreements greater than 10% between observers.

This highlights the important point that combining multiple observations made on the same data will reduce observer variability, and ultimately improve agreement with other methods. Partly for this reason, but also because to some extent the strengths and weaknesses of CTA, MRA, and duplex ultrasound are complementary, we would suggest that a combination of ultrasound and MRA should be used in preference to DSA.

What is clear from this study is that most of the disagreements are different methods of measuring carotid stenosis can be attributed to observer variability in reporting rather than to the test characteristics of the individual methods themselves. The 10% of patients injured as a result of DSA in this study, and those who continue to put at risk from catheter angiography in these circumstances, would be quite entitled to ask why they are exposed to a procedure which appears to offer no great advantage over safer alternatives. We suggest that more studies are not required, simply a more thorough understanding of presently available information.

1 Patel SG, Callie DA, Wardlaw JM, et al. Outcome, observer reliability, and patient preferences if CTA, MRA, or Doppler ultrasound were used, individually or together, instead of digital subtraction angiography before carotid endarterectomy. J Neurol Neurosurg Psychiatry 2002;73:21–8.

Author’s reply

Doctors Young and Humphrey highlight that differences between tests arise from several factors, some of which are inherent in the test and some of which arise from aspects attributable to observer variation. Some of the aspects to do with observer variation apply to interpretation of all tests and some are specific to certain tests. In our study we were endeavouring to quantify the effect on patient management if non-invasive tests were used instead of intra-arterial angiography to assess carotid stenosis. Our study has several limitations, including a relatively small sample size and the fact that we were not able to get all scans read by all observers but rather had to get pairs of observers to concentrate on reading only CTA, or MRA, or DSA. A better design would have been to keep the same workers together in pairs but randomly assign the CTA, MRA, or DSA films to each pair. As it is, it is possible that some of the apparent difference between imaging modalities is specific to the pair of observers, not to the modality. However, imaging studies are difficult to fund and expensive to do, and the result and design of our study was a compromise involving all these factors.

We identified that the observer reliability of CT angiography or MR angiography was worse than that for digital subtraction angiography, as highlighted by Drs Young and Humphrey. Also in general there was more disagreement between the observer for the reading of asymptomatic stenoses than for symptomatic stenoses (emphasising the importance of considering patient characteristics, not just the imaging technique). In the determination of the effect that this disagreement might have on patient management, we used nomograms derived from the European carotid surgery trial which were based on intra-arterial angiographic measurement of stenosis. We therefore had to use the comparison of non-invasive test reading with DSA rather than being able to use the individual observers readings of non-invasive tests. Thus as Drs Young and Humphrey point out, the actual effect of using non-invasive tests maybe worse than we have estimated.

Finally, Drs Young and Humphrey suggest that more studies are not required but we are not entirely sure that that is completely true. Non-invasive imaging tests are continually undergoing modifications, may perhaps improve risk factors, may be improvements in accuracy or practicality, but this cannot be assumed to be the case. Much of this tinkering with technology is driven by the manufacturer’s desire to encourage purchase of new machines. Improvements have also occurred in intra-arterial angiography with smaller and more manoeuvrable catheters and greater awareness of the risks, which may have helped to reduce the risk of angiography. Our “shot” of CTA, MRA, and ultrasound is already out of date because contrast MRA is now increasingly used. While we would hope that non-invasive tests (probably in combination rather than alone) would eventually replace intra-arterial angiography in the majority of patients being considered for carotid intervention, we feel it likely that there will always be a need for some intra-arterial angiography for specific cases, or depending on local resources. In any case DSA did not gain less popular than MRA among the patients in our study. There is certainly room for much more in depth examination of existing data but we shouldn’t close the door on the need for further studies.

The article by Roser et al., in which it was shown that the treatment of intracranial metastases originating from renal cell carcinoma can on occasion be successful, was most interesting.

We have followed the clinical course of a patient with a renal cell carcinoma with a low mitotic index since 1989. In this patient the course was distinctly more malignant but the disease has also been successfully treated to date. In the last 13 years, this patient has had four metastases surgically removed and a further nine treated with stereotactically guided percutaneous single dose convergent beam irradiation therapy (stereotactic modified linear accelerator, 6–15 MV photons, 18–20 Gy prescribed to the 80% isodose). Apart from slight mnemonic deficits, the patient is in good health.

The following factors which affect the prognosis were all met by our patient:

- The interval between the diagnosis of renal cell carcinoma and the first detected brain metastasis exceeds 17 months (our patient, 18 months; the patient described by Roser et al., 36 months);
- Age below 60 years at the time of initial diagnosis;
- Primary tumour of the left kidney, initial nephrectomy;
- Diameter of primary metastasis < 2 cm;
- Not more than one brain metastasis at the time of initial treatment;
- Solely intracranial metastases;
- Karnofsky > 70;
- No systemic symptoms such as fever or weight loss at the time of diagnosis;
- Blood sedimentation rate under 50 mm/h at diagnosis of renal cell carcinoma.

Patients in whom prognostic factors predict a good outcome should be treated with intent.
effects of drug therapy on cognitive and affective functioning because of the reduction in seizure activity are usually far greater than the negative effects”, more information would have been welcome in an otherwise very well balanced chapter. The book would well serve those for whom it is intended, namely, neuropathologists, neurologists, paediatric neurologists, psychologists, and other professionals who deal with patients with epilepsy. The editors rightly stress the “official line” that the majority of patients with epilepsy can achieve good control, with low associated risks.

Greenfield’s neuropathology, 7th edition

What can one say. The latest (7th) edition of Greenfield’s Neuropathology has hit the bookshops, and indeed what a resounding thud it makes! The present edition is bigger than ever, again running into two volumes, but now totalling a staggering 2330 pages and ending an equally staggering £395. It comes equipped with a handy CD version of the illustrations, a mere snip at £145.

The 7th edition has undergone considerable changes in content, since the last edition five years ago, reflecting the ever expanding increase in knowledge of diseases of the nervous system and muscle that has come from the exponential growth in neuroscience research over the past decade. Areas of cellular and molecular neurobiology, and the contributions that genetics and neuroimaging have made towards improving our understanding of the causes of disease and our clinical investigative and diagnostic skills, are more strongly featured. Hence, while greater emphasis has been placed on the basic science of disease, the classic descriptive morphology for which Greenfield is renowned is well maintained. There are new chapters on “Metabolic and neurodegenerative diseases of childhood” and “Peripheral and mitochondrial diseases”. The chapter on “Pathology of schizophrenia” has been shrewdly expanded to cover “The pathology of psychiatric disorders”. Other chapters have been retained as such, but many have been rewritten with new authors reflecting the pre-eminence of each within their particular subspecialty. There is increased reliance on colour illustrations, line diagrams and tables to illuminate the text, and these are of excellent quality throughout. As to be expected, all chapters are written authoritatively with clarity and style, comprehensively illustrated, and lavishly referenced. Judging by the content of the chapters on ageing and dementia, prion disease, and movement disorders, it is my guess that if anything is not included in each chapter, it’s probably not worth including anyway. The accompanying CD rom is user friendly, and the images are downloadable—a boon to those wishing to produce a ready made lecture or presentation of distinction. The book is a must for practicing and trainee pathologists, but is equally compelling for workers in other clinical neuroscience disciplines and basic researchers interested in the roots of the dysfunctional nervous system.

Possession of the 7th edition is guaranteed to provide a straightforward guide to chemosensation, and should serve to elevate the level of appreciation of these senses within the medical community at large.

David MA Mann

Smell and taste complaints

Despite the fact that problems with tasting and smelling are common in the general population, few physicians have the knowledge and training to authoritatively deal with them. Christopher Hawke’s Smell and Taste Complaints provides a straightforward guide to the understanding and management of chemosensory disturbances, reflecting the first clinically oriented book of its kind since Ellis Douek’s The Sense of Smell and its Abnormalities (Edinburgh: Churchill Livingstone, 1974). This 180 page pocket sized book provides a cogent overview of the anatomy and physiology of the olfactory and gustatory systems, practical approaches towards their assessment, and suggestions for therapy and management. Importantly, it provides the practitioner with the names and addresses of specialised taste and smell clinics throughout the world, aiding the referral process. Although there is little new in this guide, and much of the material seems to have been derived from second hand sources, it presents the available information in a well organised and easy to read manner. Moreover, it addresses basic clinical issues rarely addressed in a single publication. Its major drawback is the lack of reference backing for many of its statements, some of which are questionable. I found, for example, some of the “facts” unfamiliar, and would have welcomed knowledge of their source. Bits of the material are dated (for example, the role of IP, receptors in olfactory function, the nature of olfactory receptor cell regeneration) and several sections of the book seem lengthy, uncrtical, and of little practical value. Thus, nearly seven pages are devoted to the topic of odour memory, a topic with inherent theoretical issues and problems that are not addressed by the author. However, the book is not intended to be a research book and, despite such shortcomings, it accomplishes its goal of educating the practitioner and providing him or her with a practical roadmap for clinical assessment and treatment. Indeed, the clinical information provided is comprehensive and well illustrated. This inexpensive book is a must for any physician who has the occasion to see patients with chemosensory disturbances or has even a casual interest in chemosensation, and should serve to elevate the level of appreciation of these senses within the medical community at large.

Richard L Doty

The following errors occurred in the short report by Merlini L, Carbone I, Capannii C, et al. Familial isolated hyperCKaemia associated with a new mutation in the caveolin-3 (CAV-3) gene. J Neurol Neurosurg Psychiatry 2002;73:65–7. On page 66, left column, line 9, proline should replace leucine, line 12, protein should replace enzyme; and in table 1, line 8 Del-TFT (63–65) should replace TIF (63–65).

We regret that an editing error occurred in the correspondence from Jaster JH, Dohan FC, and O’Brien TF. Demyelination in the brain as a paraneoplastic disorder: candidates include some cases of seminoma and central nervous system lymphoma. J Neurol Neurosurg Psychiatry 2002;73:332. The description of a patient expanded, altered, in the first line of the fourth paragraph the text should read “ . . . patient who had a non-neurological malignancy, seminoma, and subsequently developed a paraneoplastic syndrome . . . “.
