Clinical application of neuroimaging in epilepsy

U C Wieshmann

Objective: To evaluate the use of neuroimaging in clinical practice and to assess the prevalence of detected structural abnormalities in epilepsy patients in a clinical set up.

Methods: 919 outpatients were identified and the scan results reviewed. A total of 677 patients had chronic active epilepsy (88 had idiopathic generalised epilepsy (IGE), 588 had localisation related epilepsy, one had symptomatic generalised epilepsy), 57 had a single epileptic seizure, 46 were in remission, and 139 had non-epileptic attacks.

Results: 391 patients had no scan (53 patients in this group had IGE, 182 had localisation related epilepsy, one had generalised symptomatic epilepsy, 18 had single epileptic seizures, 21 were in remission, 116 had non-epileptic attacks). Altogether 528 patients had a scan, the results were not available in 33, 163 had x ray computed tomography (CT) only, 178 had standard magnetic resonance imaging (MRI) (slice thickness 5 mm), and 154 had high resolution MRI (including a T1 weighted sequence with 1.5 mm thick slices). Some 252 of 495 scans (51%) were abnormal. Abnormalities were hippocampal sclerosis (n=128), atrophy or non-specific white matter lesions (n=35), vascular abnormalities (n=27), tumours (n=25), brain damage (n=24), malformations of cortical development (n=13). Excluding atrophy and non-specific white matter lesions the prevalence of detected abnormalities was 54% in localisation related epilepsy, 18% in single seizure patients, 16% in epilepsy in remission, and 0% in IGE and non-epileptic attacks.

Conclusions: Abnormalities were detected in more than half of all patients with localisation related epilepsy, and in about one in five patients with single seizures or epilepsy in remission. Many patients had no scan or only CT or standard MRI. The true prevalence of structural abnormalities may be have been higher. Scanning did not add any information in patients with IGE or non-epileptic attacks.

Structural cerebral abnormalities can often be detected in epilepsy patients with modern neuroimaging techniques. Tumours, infarcts, and major malformations are usually detectable on x ray computed tomography (CT) imaging. Magnetic resonance imaging (MRI) using appropriate sequences also permits the detection of more subtle abnormalities such as hippocampal sclerosis, subependymal nodular and band heterotopia, focal cortical dysplasia and small tumours including dysembryoplastic neuroepithelial tumours (for review see Duncan). Imaging studies performed at research centres suggested a high prevalence of structural abnormalities in patients with epilepsy. The results of research studies are not directly applicable to clinical routine because such studies differ from clinical routine in various ways. Research studies may suffer from selection bias, favouring patients with potential cerebral abnormalities. On the other hand, the imaging modalities applied in research studies are likely to be optimal for the detection of abnormalities and the scans are likely to be reviewed by specialists with an interest in epilepsy. This may not necessarily apply for clinical routine work. Neuroimaging guidelines have been published but the use of neuroimaging and the prevalence of detected abnormalities in a clinical environment are unknown. The aim of this paper was to review the use of neuroimaging and to assess the prevalence of detected structural abnormalities in a clinical hospital outpatient setting.

METHODS

For this cross sectional study we included patients with chronic active epilepsy, a single epileptic seizure, epilepsy in remission (no seizures for two years or longer) or non-epileptic seizures. For the purpose of this study patients suffering from non-epileptic attack disorder and patients with faints or other transient non-epileptic episodes were summarised under non-epileptic seizures. Chronic active epilepsies (recurrent seizures despite anticonvulsive treatment) were further classified as idiopathic generalised epilepsy (IGE) or other forms of epilepsy.

The imaging reports were reviewed. It was clarified who produced the report (that is, a trained neuroradiologists or a general radiologist). The imaging modality was identified—that is, cranial x ray computed tomography, standard MRI with slice thickness 5 mm (standard MRI), or high resolution MRI with one T1 weighted sequence with slice thickness 1.5 mm.

The neuroradiological findings were classified as normal, consistent with hippocampal sclerosis, vascular abnormality (including infarct, arterio venous malformation, cavernous haemangioma), tumour, malformation of cortical development (including focal cortical dysplasia, schizencephaly, subependymal nodular and band heterotopia), brain damage, or non-specific abnormality (including white matter lesions).

RESULTS

Clinical data

A total of 919 patients were identified. The mean age was 39.7 years (median 39, minimum 15, maximum 87 years, standard deviation 14.2 years). Some 603 were seen at specialist epilepsy clinics (190 had been considered for epilepsy surgery), 316 patients were seen at general neurology clinics by one neurologist. Altogether 677 patients had chronic active epilepsy, 88 patients had IGE, 589 patients suffered from epilepsies other than IGE (all but one patient in this group had localisation related cryptogenic or symptomatic epilepsy, there were no patients with Rolandic epilepsy). Fifty seven patients
had single epileptic attacks, 46 were in remission, and 139 patients were classified as suffering from non-epileptic attacks. There was no overlap between the groups. The patients in remission were not included in the categories of attacks. There were no epileptic attacks in remission (Remission), single epileptic attack (Single), non-epileptic attacks (NES)). Only abnormalities relevant to epilepsy were included. (Hippocampal sclerosis, tumours, malformations, vascular abnormalities, non-specific white matter lesion, and atrophy were not included in this graph.) MRI+ abnormality on MRI detected; MRI-, no relevant abnormality detected; CT+, abnormality detected; CT-, no abnormality detected; no scan, no imaging performed; no result, scan result not available.

Figure 1  Stacked graph showing the number of patients with abnormal scans, normal scans, no scans, and unavailable results as a proportion of the total number for the different groups (localisation related epilepsy [LRE]*, idiopathic generalised epilepsy [IGE], epilepsy in remission [Remission], single epileptic attack [Single attack], non-epileptic attacks [NES]). Only abnormalities relevant to epilepsy were included. (Hippocampal sclerosis, tumours, malformations, vascular abnormalities, non-specific white matter lesion, and atrophy were not included in this graph.) MRI+, abnormality on MRI detected; MRI-, no relevant abnormality detected; CT+, abnormality detected; CT-, no abnormality detected; no scan, no imaging performed; no result, scan result not available. *LRE includes the single patient with symptomatic generalised epilepsy.

CT imaging was performed on a Philips CT scanner. Intravenous contrast was given if a focal onset was indicated on the request form. Axial images were obtained. Standard MRI was performed on a Siemens Magnetom or a GE 1.5 Tesla scanner. Sagittal T1 weighted images and axial T2 weighted and proton density weighted images were obtained in all patients. In some patients coronal T1 weighted images and coronal fluid attenuated inversion recovery (FLAIR) images were also obtained. All images had a slice thickness of 5 mm (typical matrix 192×256 and typical FOV 25 cm). Intravenous contrast was given in a minority of patients (usually with mass lesions). A small group of patients had CT or standard MRI investigations using similar protocols at other hospitals. High resolution MRI (slice thickness 1.5 mm) imaging was performed on a GE 1.5 T scanner. Coronal T1 weighted contiguous images with 1.5 mm slice thickness and coronal T2 weighted, proton density weighted, and FLAIR images with 5 mm slice thickness were obtained. Measurements of hippocampal T2 relaxation time and volume were performed using previously described methods. Normal limits of hippocampal volume and T2 relaxation time were established from 73 controls. Hippocampal measurements in a patient outside the 99% confidence intervals in controls were considered abnormal. All images had been reported by neuroradiologists.

Scan results

Some 252 of the 495 reviewed scan results (51%) were abnormal.

Chronic active localisation related epilepsy

Abnormalities were most frequently detected in this group (58% abnormalities). This group had the most favourable MRI:CT ratio of around 3 to 1 and had all but two high resolution MRI (slice thickness 1.5 mm) scans.

Single attack

Abnormalities were detected in one of three of all patients with single epileptic attacks, most had non-specific abnormalities or cerebrovascular accidents. Two had tumours. One patient (of four patients under 20) was a 17 year old with a single generalised nocturnal seizure. This patient had a presumed oligodendroglioma in the right posterior temporal region. There were no signs on examination, the EEG was normal. The lesion was detected on CT and confirmed on standard MRI. Another 29 year old patient in the single attack group had a large right temporal arterio venous malformation. The initial investigation in this patient was a standard MRI, CT was not performed.

Remission

In more than 80% no abnormality was detected. Abnormalities were usually non-specific, two had vascular lesions (there was one patient who had an excision of an arterio venous malformation and one had a cerebrovascular accident) one patient had brain damage.

| Table 1  Abnormal scans, excluding atrophy and non-specific white matter lesions |
|---------------------------------|-----------------|-----------------|-----------------|
| Abnormal/Total (%)             | All scans       | CT only         | sMRI            | hMRI            |
|--------------------------------|-----------------|-----------------|-----------------|
| LRE                            | 207/387 (54)    | 28/93 (30)      | 69/142 (49)     | 110/152 (72)   |
| IGE                            | 0/31 (0)        | 0/17 (0)        | 0/13 (0)        | 0/1 (0)        |
| Single                         | 7/40 (18)       | 5/31 (16)       | 2/9 (22)        | N/A            |

| Total                          | 217/495 (44)    | 35/163 (22)     | 72/178 (40)     | 110/154 (71)   |

CT, computed tomography; sMRI, standard magnetic resonance imaging with 5 mm thick slices; hMRI, high resolution MRI with 1.5 mm thick slices; LRE, localisation related epilepsy; IGE, idiopathic generalised epilepsy; Remission, epilepsy in remission; Single, single epileptic attack; NES, non-epileptic attack.
Non-epileptic attacks

Only in 17% of patients with non-epileptic attacks were abnormalities detected, all were non-specific white matter lesions.

IGE

All but one IGE patient had normal scan reports. The detected abnormality was a single small non-specific white matter lesion in the brain stem of uncertain significance (table 1).

Detected abnormalities

The most commonly detected abnormality was hippocampal sclerosis (n=128), followed by non-specific abnormalities (n=35), vascular abnormalities (n=27), tumours (n=25), malformations of cortical development (n=12), and other abnormalities were infrequent in this group of patients who were all considered for epilepsy surgery. There was one patient who had a small temporal glioma, which was only detected on high resolution MRI. Hippocampal sclerosis was occasionally detected with standard MRI, but not with structural abnormalities, patients often had only CT and some structural abnormalities such as atrophy may only develop after the onset of epilepsy. However, a substantial minority of patients with single seizures had abnormalities (18%), a result similar to the result published by King et al who found 38 lesions in 300 patients with single attacks. Hopkins suggested that people who have had a first seizure should be scanned if the clinical onset of the seizure was clearly partial and no evidence of previous scanning was found. About 30% of all patients with localisation related epilepsy were not scanned. The rationale for imaging the brain of patients developing epilepsy is first to identify underlying abnormalities such as vascular lesions and tumours that require specific treatment and second to assist the formulation of syndromic and aetiological diagnosis. King et al. found that patients with localisation related epilepsy who were scanned with high resolution MRI, the prevalence of detected abnormalities was almost 80%, similar to the prevalence reported by Li et al. It has to be kept in mind that these patients were suffering from severe epilepsy and were highly selected. This group was therefore not representative for epilepsy as a whole. Nevertheless, our study underlined the value of scanning patients with localisation related epilepsy in the clinical setting. In our study 182 patients with localisation related epilepsy were not scanned at all, which is not in accordance with accepted guidelines and raises important clinical governance issues.

In patients with single epileptic seizures the yield of neuroimaging as used in our study was lower than in localisation related epilepsy. Several factors may explain the difference. Some patients with single attacks probably will develop IGE, patients with single attacks may have a more benign form of epilepsy that may be less likely to be associated with structural abnormalities. Patients often had only CT imaging and subtle abnormalities may have been overlooked and some structural abnormalities such as atrophy may only develop after the onset of epilepsy. However, a substantial minority of patients with single seizures had abnormalities (18%), a result similar to the result published by King et al who found 38 lesions in 300 patients with single attacks. Hopkins suggested that people who have had a first seizure should be scanned if the clinical onset of the seizure was clearly partial or if there are focal neurological signs that are not clearly accounted for by known pre-existing neurological damage such as cerebral palsy or embolus. Following this protocol the vast majority of abnormalities would be detected. However, a small minority of potentially treatable abnormalities may be missed. In our study two patients with single seizures had tumours, one was under the age of 20 and had no localising...
Clinical imaging in epilepsy

No abnormalities were detected in patients with IGE or patients with non-epileptic seizures. Almost 40% and about 20% respectively had scans in these groups. Uncertainty about the diagnosis may explain why the scans were requested. Fourier MRI does not add information in patients with IGE or Rolandic epilepsy and routine MRI is not recommended in those patients. New MRI techniques may lead to clinical applications of neuroimaging in IGE in the future but there is no clinical application at present. Early clinical classification, supported by EEG, is important to avoid unnecessary imaging investigations. Occasionally the EEG may show bilaterally synchronous discharges in patients with focal lesions, which may lead to the erroneous diagnosis of IGE. The diagnosis should be reviewed and imaging performed in all patients where the seizure semiology or treatment response is unusual for IGE or Rolandic epilepsy.

The other main finding was the frequent use of CT and standard MRI with 5 mm thick slices in the clinical setting. About one third (163 patients) of all patients who had scans had only a cranial CT investigation, one third had a standard MRI with 5 mm thick slices, usually with CT (178 patients) and one third (154 patients) had a high resolution MRI including a T1 weighted sequence with 1.5 mm slice thickness. Since the initial application in 1984, the superiority of MRI over x-ray CT in terms of sensitivity and specificity for identifying the aetiology of epilepsy has become firmly established. Epileptogenic lesions may be missed in patients who had only CT or standard MRI. Hippocampal sclerosis, small low grade gliomas or small arterio-venous malformations and malformations of cortical development are all difficult to detect on CT. In addition a CT examination of the head involves a radiation dose of 2.3 mSV, which equals more than 100 chest radiographs or the background radiation of about one year. MRI should therefore be the examination of choice in patients with epilepsy. CT may retain a role as the initial investigation if MRI is not possible because of claustrophobia, learning disability, acute disorders such as status epilepticus, contraindication for MRI, or if MRI is not available within reasonable time. CT also retains a role, supplementary to MRI, in the recognition of intracranial calcifications that may not be easily detected on MR images. Calculified tubers in tuberous sclerosis, which is commonly associated with epilepsy, are more conspicuous on CT images than MRI. This was again illustrated in our study. A calcified tuber was initially overlooked on MRI but later detected on CT. Calcifications also commonly occur in neurocysticercosis, worldwide a main cause of epilepsy. Now MRI techniques such as magnetisation transfer imaging may increase the yield of MRI in neurocysticercosis and possible replace CT.

MRI is a versatile diagnostic tool and it is important to choose the appropriate imaging parameters to get optimal results in epilepsy. Important abnormalities such as hippocampal sclerosis, subcortical cortical dysplasias, and band heterotopia may be difficult to detect on standard MRI and high resolution MRI (slice thickness 1.5 mm) is the method of choice. The sensitivity of MRI for hippocampal sclerosis can be further improved by the use of FLAIR. The limitations of standard MRI to detect hippocampal sclerosis were again highlighted in our study. The standard MRI scan of a patient with hippocampal sclerosis on postmortem examination was initially reported as normal. The recommendation to use MRI with thin slices (and preferably including a FLAIR sequence) was therefore supported by our data in the clinical setting. These MRI sequences are readily available on clinic MRI scanners and add only a few minutes to the examination. MRI and magnetic resonance spectroscopy are developing techniques. Other magnetic resonance techniques such as diffusion imaging, functional MRI, quantitative measurements of volume of structures and T2 relaxation time, serial MRI, or spectroscopy and multi-modal imaging have all been used in epilepsy research and may gain a clinical role in selected epilepsy patients in the future.

Summary

In our clinical setting many patients with localisation related epilepsy had no scan or were only scanned with CT or standard MRI which are less sensitive for important epileptogenic lesion than high resolution MRI. Our study provided further examples where high resolution MRI was superior to other imaging modalities. An MRI protocol for epilepsy should include at least one sequence with coronal T1 weighted thin slices (slice thickness 1 mm to 2 mm). A significant minority of patients with non-epileptic seizures and IGE were scanned but imaging did not add any relevant abnormalities.

Neuroimaging detected abnormalities in most patients with localisation related epilepsy and in a sizeable number of patients with single seizures and epilepsy in remission. Our study underlined the importance of optimal neuroimaging for these patients.

ACKNOWLEDGEMENTS

I would like to thank Dr Tom Nixon for his support and helpful comments and Professor David Chadwick for his helpful comments.
