Vestibular activation by bone conducted sound

M S Welgampola, S M Rosengren, G M Halmagyi, J G Colebatch

Objective: To examine the properties and potential clinical uses of myogenic potentials to bone conducted sound.

Methods: Myogenic potentials were recorded from normal volunteers, using bone conducted tone bursts of 7 ms duration and 250–2000 Hz frequencies delivered over the mastoid processes by an 871 clinical bone vibrator. Biphasic positive-negative (p1n1) responses were recorded from both sternocleidomastoid (SCM) muscles using averaged unrectified EMG. The best location for stimulus delivery, optimum stimulus frequency, stimulus thresholds, and the effect of aging on evoked response amplitudes and thresholds were systematically examined. Subjects with specific lesions were studied. Vestibular evoked myogenic potentials (VEMP) to air conducted 0.1 ms clicks, 7 ms/250–2000 Hz tones, and forehead taps were measured for comparison.

Results: Bone conducted sound evoked short latency p1n1 responses in both SCM muscles. Ipsilateral responses occurred earlier and were usually larger. Mean (SD) p1 and n1 latencies were 13.6 (1.8) and 22.3 (1.2) ms ipsilaterally and 14.9 (2.1) and 23.7 (2.7) ms contralaterally. Stimuli of 250 Hz delivered over the mastoid process, posterosuperior to the external acoustic meatus, yielded the largest amplitude responses. Like VEMP in response to air conducted clicks and tones, p1n1 responses were absent ipsilaterally in subjects with selective vestibular neuritis and preserved in those with severe sensorineural hearing loss. However, p1n1 responses were preserved in conductive hearing loss, whereas VEMP to air conducted sound were abolished or attenuated. Bone conducted response thresholds were 97.5 (3.9) dB SPL/30.5 dB HL, significantly lower than thresholds to air conducted clicks (131.7 (4.9) dB SPL/86.7 dB HL) and tones (114.0 (5.3) dB SPL/106 dB HL).

Conclusions: Bone conducted sound evokes p1n1 responses (bone conducted VEMP) which are a useful measure of vestibular function, especially in the presence of conductive hearing loss. For a given perceptual intensity, bone conducted sound activates the vestibular apparatus more effectively than air conducted sound.

The assessment of patients with vertigo and disequilibrium can be challenging, and the availability of investigations that examine each component of the vestibular apparatus would facilitate a more complete examination. Vestibulo-ocular reflexes (VOR) to caloric stimulation and sinusoidal rotation have long been in clinical use as measures of lateral semicircular canal function. More recently, impulsive tests which measure VOR to rapid head accelerations in the plane of each semicircular canal have allowed measurement of individual canal function. Clinically useful techniques that assess otolith function, however, are few and not widely available. The click evoked myogenic potential—a relatively recently developed simple, non-invasive test of otolith function—is based on the acoustic sensitivity of the sacculus.

Intense clicks delivered through headphones evoke vestibular dependent, biphasic potentials (p3n23) recordable from the sternocleidomastoid (SCM) muscles ipsilateral to the stimulated ear, during tonic activation (vestibular evoked myogenic potentials (VEMP); Colebatch et al, 1994). Their short onset latency of about 8 ms suggests that these responses are mediated by an oligosynaptic arc, which probably consists of the primary vestibular afferents synapsing at the vestibular nuclei, the second order vestibulococulor neurons, and the neck motor nerves innervating the SCM. Intense short tone bursts delivered through headphones also evoke VEMP which have similar properties to those evoked by clicks when stimuli of appropriate frequency and duration are used. Both click evoked and tone burst evoked responses require the integrity of middle ear conductive mechanism to convey the stimulus to the vestibular end organs. To enable measurement of VEMP in subjects with conductive hearing loss, Halmagyi et al proposed the use of forehead taps delivered through a modified reflex hammer, which probably results in a wave of vibration that is directly conveyed to both labyrinths, circumventing the middle ear conductive apparatus. This stimulus evokes an initial positivity (p1) followed by two negativities (“n1,n2,” see fig 1), of which only the first is vestibular dependent. The precise vestibular afferents stimulated by a forehead tap have not been established, although an otolith contribution is likely, given the similarity of the waveform to that of the click evoked response. Sheykholeslami et al recently reported that tone bursts delivered by a clinical bone vibrator applied over the mastoid process give rise to short latency potentials in the SCM, which were likely to be of vestibular origin. This new technique holds promise as an alternative to the tap evoked response, as a method of eliciting vestibular dependent responses in subjects with conductive hearing loss. It has the advantage of being a calibrated and reproducible stimulus and therefore should elicit consistent responses and enable the measurement of stimulus thresholds.

The emergence of several related methods of evoking vestibulococulor reflexes necessitates assessment of their relative merits and definition of the place of each these techniques in vestibular function testing. Our aim in the present study was to examine further the properties of responses evoked by bone conducted sound. We confirmed the vestibular dependence and defined the optimum stimulus parameters, methods of

METHODS

Ten healthy adults aged 24 to 52 years (five men, five women) were studied after obtaining informed consent and local ethics committee approval.

Myogenic potentials to 7 ms/500 Hz/112 dB SPL (sound pressure level) tone bursts delivered by a clinical bone vibrator (B71, Radioear Corporation, New Eagle, Pennsylvania, USA) placed on the mastoid process (3 cm posterior to the external acoustic meatus) were recorded from all subjects. VEMP to clicks of 0.1 ms/145 dB SPL (= 100 dB normal hearing level (NHL)) and 7 ms/500 Hz tone bursts of 123.5 dB SPL delivered through headphones (our “standard parameters” for these stimuli) and forehead taps were also measured for comparison.

To determine whether bone conducted tone burst evoked response amplitudes also increase linearly with EMG activity, responses to standard stimuli were measured in five subjects, using a grid consisting of 12 points around the external auditory meatus (approximately 20, 40, 60, 80, and 100 µV). Peak to peak amplitudes were plotted against mean rectified EMG. To control for differences in activation, the effects of varying different parameters were systematically investigated. Using the standard parameters, myogenic responses were recorded in five subjects with the bone vibrator placed on Fpz, the anterior temporal region (approximately 2 cm above and 4 cm anterior to the external acoustic meatus), the mastoid processes (3 cm posterior to the external acoustic meatus), and the external occipital protuberance. The best location for delivery of the stimulus was mapped in greater detail in 10 subjects, using a grid consisting of 12 points around the external acoustic meatus.

In the present study, results are presented as both raw (uncorrected) amplitudes and corrected reflex amplitudes. Side to side differences in corrected amplitudes were expressed as an asymmetry ratio (AR); where A, and A, were the larger and the smaller amplitudes of the left and right sides,

\[
AR = 100 \times \left( \frac{A_l - A_r}{A_l + A_r} \right)
\]

Myogenic potentials evoked by bone conducted sound

Tone bursts were generated using a Jupiter 2010 function generator (Black Star, Cambridge, UK); these were amplified and gated electronically. The onset and offset of the gate were fixed and were independent of the phase of the input. Bone conducted stimuli were delivered using a 7B1 clinical bone vibrator previously calibrated using a Bruel and Kjaer (model BMK4930) artificial mastoid. An initial study was undertaken using stimuli of 7 ms duration/500 Hz/112 dB SPL ("standard parameters") delivered at three per second; these were based upon the optimum parameters for air conducted tone bursts.

To determine whether bone conducted tone burst evoked response amplitudes also increase linearly with EMG activity, responses to standard stimuli were measured in five subjects, while maintaining different degrees of background activation (approximately 20, 40, 60, 80, and 100 µV). Peak to peak amplitudes were plotted against mean rectified EMG activity. In addition, one subject was studied at 15 different levels of activation corresponding to mean rectified EMG levels of 15 µV to 150 µV. Myogenic potentials were measured in two separate experiments done seven to 10 days apart in 10 subjects to assess between-experiment reproducibility. Reproducibility of tap evoked responses was also examined for comparison.

To determine the optimum stimulus frequency, responses to 250, 500, 1000, and 2000 Hz bone conducted tone bursts were directly comparable, we have expressed all intensities in dB SPL.
measured in 10 subjects. Stimuli of nearly constant intensities were used (that is, 107.5, 107, 107.5, and 105.5 dB SPL, corresponding to 20, 5, 10, and 10 volts peak to peak respectively at 250, 500, 1000, and 2000 Hz). These stimuli, generated digitally, were phase locked at 0° and had 1 ms rise and fall times and a 7 ms hold time. In each subject, the optimum stimulus frequency was determined and stimulus thresholds were measured at this frequency using 6 dB decrements in intensity.

We have previously reported clear effects of age on VEMP amplitudes and thresholds. Therefore myogenic potentials to bone conducted sound were measured in 10 older subjects aged 63 to 83 years (mean (SD), 71.6 (6.7)), using 7 ms/500 and 1000 Hz tones of 10 V p–p (equivalent to 112 and 107.5 dB SPL). These frequencies, at which the bone conductor had its greatest output, were chosen to enable more effective stimulation. Those who had no response to stimuli with these parameters were studied using more intense stimuli of 20 V p–p (115 and 112 dB at 500 and 1000 Hz). Stimulus thresholds were also measured. VEMP to air conducted tones with similar parameters were recorded and thresholds measured for comparison.

We measured responses (net potentials) to combined air and bone conducted tones delivered to the same ear at varying degrees of phase advance of the bone conducted tone, using 20° increments. Air and bone conducted tones (7 ms/500 Hz) with intensities that evoked responses of comparable amplitudes were used. The amplitude of the net potential to the combined stimuli was measured. Decreases in the net potential were interpreted as evidence of phase cancellation of the stimuli.

Patients with specific lesions

Responses to clicks (145 dB SPL) and to air and bone conducted tones with the standard parameters were measured in four subjects who had undergone selective unilateral vestibular neurectomy, in six subjects with conductive hearing loss (“air–bone gaps” of 10–40 dB), and in four subjects with profound sensorineural hearing loss. Four subjects (five ears) with the “Tullio” phenomenon secondary to superior semicircular canal dehiscence had stimulus thresholds measured to clicks, air conducted tones, and bone conducted tones. One subject with a bilateral near total vestibulopathology, who had marked reduction of caloric responses and decreased VOR in the planes of all six semicircular canals (Cremer P, personal communication), was studied using air conducted clicks and tones and bone conducted tones.

VEMP evoked by air conducted clicks, tones, and forehead taps

VEMP to clicks and tone bursts delivered through headphones were measured in all 10 subjects. The clicks of 0.1 ms duration and 145 dB SPL (100 dB NHL) were generated using an ST 10 evoked potential stimulator (Medelec, Surrey, UK) and tone bursts of 2 V p–p intensity (123, 123.5, 124, and 125 dB SPL at 250, 500, 1000, and 2000 Hz) were generated using the function generator. During each recording, stimuli were presented pseudorandomly in each ear at five per second through calibrated headphones (TDH 49, Telephonics Corp, New York, USA) and responses to 512 stimuli (256 in each ear) were averaged. Frequency tuning properties of air conducted tones were examined using the same methods as for bone conducted tones. Click and air conducted tone thresholds were measured using 5 dB and 6 dB decrements, respectively.

Forehead taps were delivered manually through a small gauze pad placed approximately over Fpz, using a nylon handled reflex hammer fitted with an inertial trigger switch. Responses to 64 stimuli were averaged. In subjects who did not have two separate negative peaks (p1 and n1), a slur on the upstroke leading to the negativity or a point at which a clear change in the slope of the upstroke occurred was marked as n1. Data of subjects who had “non-separating” peaks without these features were treated as missing values.

Statistical methods

SPSS version 9 (SPSS Inc, Chicago, Illinois, USA) was used for all data analyses. To examine the effects of varying location and frequency, repeated measures analysis of variance (ANOVA) with contrasts were done using the corrected reflex amplitudes as the dependent variables and stimulus location or stimulus frequency as fixed factors. A significance level of 0.05 was used, with Bonferroni corrections for multiple comparisons. All results are given as mean (SD) unless otherwise noted.

RESULTS

Properties of bone conducted responses and comparison with VEMP to other stimuli

All 10 subjects had short latency biphasic positive-negative (p1n1) responses to bone conducted tone bursts of standard parameters, which were present bilaterally. Later responses were also present but will not be discussed further. Eight subjects had larger amplitude bone conducted responses recorded from the SCM ipsilateral to the stimulus and smaller ones from the contralateral SCM (see fig 1) and two had the reverse. All subjects had VEMP to clicks and “air conducted” tone bursts of standard parameters recorded from the SCM ipsilateral to the side of stimulation. Seven of the 10 subjects had measurable VEMP to forehead taps recorded from both SCM, two had measurable VEMP on one side (SCM) only. There were four “non-separating” responses (two unilateral and one bilateral).

Bone conducted tones evoked myogenic responses, which had significantly higher average corrected amplitudes (mean (SD), 1.36 (0.45)) recorded from the SCM ipsilateral to the stimulus compared with the contralateral SCM (0.93 (0.66)) (p < 0.001). Raw amplitudes were 77.0 (26.2) µV ipsilaterally and 55.2 (34.8) µV contralaterally. Peak latencies recorded from the SCM ipsilateral to the stimulus occurred earlier (average p1 and n1 of 13.6 (1.8) ms and 22.3 (1.2) ms) compared with those recorded over the contralateral SCM (p1 and n1 of 14.9 (2.1) and 23.7 (2.7) ms). The range for p1 latencies was 11.9 to 16.5 ms ipsilaterally and 12.5 to 19.6 ms contralaterally, and that for n1 latencies was 20.0 to 26.6 ms ipsilaterally and 20.1 to 30.2 ms contralaterally.

The average corrected amplitudes for click, tap, and air conducted tone burst evoked responses were 1.98 (0.48), 2.4 (0.52), and 1.3 (0.52) µV (raw amplitudes of 130.4 (32.9), 247.0 (61.2), and 78.3 (32.8) µV, respectively). The average peak latencies (p1n1) responses to bone conducted tone bursts of standard parameters, which were present bilaterally. Later responses were also present but will not be discussed further. Eight subjects had larger amplitude bone conducted responses recorded from the SCM ipsilateral to the stimulus and smaller ones from the contralateral SCM (see fig 1) and two had the reverse. All subjects had VEMP to clicks and “air conducted” tone bursts of standard parameters recorded from the SCM ipsilateral to the side of stimulation. Seven of the 10 subjects had measurable VEMP to forehead taps recorded from both SCM, two had measurable VEMP on one side (SCM) only. There were four “non-separating” responses (two unilateral and one bilateral).

Bone conducted tones evoked myogenic responses, which had significantly higher average corrected amplitudes (mean (SD), 1.36 (0.45)) recorded from the SCM ipsilateral to the stimulus compared with the contralateral SCM (0.93 (0.66)) (p < 0.001). Raw amplitudes were 77.0 (26.2) µV ipsilaterally and 55.2 (34.8) µV contralaterally. Peak latencies recorded from the SCM ipsilateral to the stimulus occurred earlier (average p1 and n1 of 13.6 (1.8) ms and 22.3 (1.2) ms) compared with those recorded over the contralateral SCM (p1 and n1 of 14.9 (2.1) and 23.7 (2.7) ms). The range for p1 latencies was 11.9 to 16.5 ms ipsilaterally and 12.5 to 19.6 ms contralaterally, and that for n1 latencies was 20.0 to 26.6 ms ipsilaterally and 20.1 to 30.2 ms contralaterally.

Three of the four subjects who had undergone selective vestibular neurectomy were generated as a treatment for intractable vertigo had absent short latency bone conducted responses in the ipsilateral SCM on stimulation of the mastoid on the side of the lesion. On stimulation of the intact side, p1n1 responses were present on that same side only. One of these three subjects, when stimulated over the operated side, had no response ipsilaterally but a well formed p1n1 response was recorded from the contralateral SCM, presumably due to bone conduction of the tone to the opposite labyrinth (fig 2). A fourth subject who had undergone selective vestibular neurectomy had a small p1n1 response recorded from the ipsilateral SCM following stimulation of the side of the lesion, but this finding was not reproducible on repeated recordings. The subject was also found to have residual posterior semicircular canal function on impulsive testing, suggesting residual nerve function related to the inferior division of the vestibular nerve (Cremer et al., 1985).
P, personal communication). As with click and tone burst evoked VEMP, short latency responses to bone conducted sound were preserved in the four subjects with severe sensorineural hearing loss. The above findings confirm the conclusions of Sheykholeslami et al. that short latency p1n1 myogenic responses to bone conducted sound are vestibular dependent and we shall henceforth refer to them as “bone conducted VEMP”.

All five subjects tested for the effect of stimulus location had bone conducted VEMP to the standard stimulus parameters when the bone conductor was placed on the mastoid process (3 cm posterior to the external acoustic meatus). When stimulated over the temporal and occipital regions, ipsilateral bone conducted VEMP were obtainable only in three and two of the five subjects, respectively. Stimulation over Fpz resulted in bilateral responses in three of the five subjects, a unilateral response in one, and absent responses in the other. The average corrected VEMP amplitudes for the mastoid, frontal, anterior temporal, and occipital regions were 1.22, 0.32, 0.36, and 0.31, respectively. Raw amplitudes were 76.0, 44.0, 14.0, and 6.5 µV, respectively. Upon detailed mapping of amplitudes, when the stimulus was applied at 12 different locations in relation to the external acoustic meatus, larger bone conducted VEMP were recorded from locations superior and posterior to the meatus (fig 3). A location 3 cm behind and 2 cm above the external acoustic meatus yielded the highest average VEMP amplitude for the 10 subjects, although the best site varied between subjects. A significant effect of location was present on ANOVA ($F_{11, 99} = 16.5, p < 0.001$). On simple contrasts between VEMP amplitudes at the optimum location and the remaining sites, there were significant differences between it and eight of the remaining 11 locations. There were no significant differences between the amplitude at the optimum site and those at three other locations (“optimum locations”). These formed an inverted L behind and above the external acoustic meatus and were located 3 cm behind, 3 cm behind and 2 cm above, 3 cm behind and 4 cm above, and 4 cm directly above the external acoustic meatus, respectively (fig 3).

The peak to peak amplitudes of bone conducted VEMP increased linearly with increasing mean rectified EMG activity.
Correlation coefficients \((r)\) between SCM activation and peak to peak amplitudes in the same subject ranged from 0.9 to 0.99. In the subject who was tested at 15 different levels of background activation (18 to 155 µV), the raw peak to peak amplitudes varied from 21.1 to 262 µV (12-fold). The corrected amplitudes only varied from 1.1 to 1.9 (1.7-fold), confirming that this measure was more constant and less likely to be influenced by EMG activity when compared with raw amplitudes. Correlation of VEMP amplitudes to the standard stimulus obtained on two separate days (approximately one week apart) for 10 subjects resulted in a coefficient of 0.77 \((p < 0.001)\) for bone conducted VEMP \((n = 10)\). A similar correlation coefficient \((0.71)\) was obtained for tap evoked responses \((n = 10)\). The tendency to have larger VEMP recorded from the contralateral SCM, observed in two subjects, was not reproducible between experiments.

**Frequency tuning properties and side to side differences**

Average corrected VEMP amplitudes recorded from the ipsilateral SCM for 7 ms/250, 500, 1000, and 2000 Hz bone conducted tones \((107 \text{ dB nominally})\) were 1.43 (0.2), 0.68 (0.2), 0.88 (0.2), and 0.30 (0.1), respectively \((\text{fig 5})\). Average raw amplitudes were 104.4 (60.2), 58.1 (54.7), 70.2 (47.0), and 24.1 (15.9) µV, respectively. Differences between reflex amplitudes measured at the four stimulus frequencies were much greater than the slight differences in stimulus intensity for each frequency \((\text{see Methods})\). In contrast to air conducted tones \((\text{fig 5})\), the largest response was at 250 Hz. On ANOVA with contrasts, average VEMP amplitudes in response to the 250 Hz stimulus were significantly higher than average amplitudes obtained with the other three stimuli \((F_{3,27} = 41.64, p < 0.001)\). There was no significant difference between responses to 500 and 1000 Hz stimuli \((p = 0.56)\). The optimum stimulus frequency was 250 Hz for 17 sides and 1000 Hz for three sides. Mean thresholds for bone conducted tones were 97.5 (3.9) dB SPL (30.5 dB HL) \((\text{hearing level})\) when measured using the 250 Hz stimulus and 100.3 (5.0) dB SPL \((42.3 \text{ dB HL})\) using a 500 Hz stimulus. Thresholds for clicks and air conducted tones were significantly higher at 131.7 (4.9) dB SPL \((86.7 \text{ dB NHL})\) and 114 (5.3) dB SPL \((106 \text{ dB HL})\), respectively \((\text{fig 6})\).

Asymmetry ratios for bone conducted tones were calculated using the VEMP amplitudes recorded from the SCM ipsilateral to the stimulus. The average asymmetry ratios for bone conducted tones were 17.3% \((\text{range 0 to 58.2})\), 38.5% \((0\) to...
Thresholds to three modes of stimulation. Normal subjects had click thresholds ranging from 120 to 135 dB SPL, air conducted tone thresholds of 106 to 124 dB SPL, and bone conducted thresholds of 95 to 107.5 dB SPL at 500 Hz. The click thresholds for subjects with the Tullio phenomenon were 105 to 110 dB SPL and air and bone conducted thresholds were 88 to 94 dB SPL and 83 to 95 dB SPL, respectively. While the click and air conducted tone thresholds in Tullio subjects were at least 10 dB below the lowest normal threshold, those for bone conducted tones approached normal levels in two of the five ears tested.

We were able to demonstrate modest phase cancellation between air and bone conducted tone burst evoked responses. For the three subjects tested, average reflex amplitudes to the air conducted stimulus alone, bone conducted sound alone, and the maximum net potential obtained with the combined stimulus were 1.01, 1.06, and 2.38, respectively. Thus the maximum net potential approximated the sum of the responses to air and bone conducted sound. For subject 1, the maximum corrected amplitude for the net potential was 2.77 at intervals of 60° and 120°; the minimum amplitude was 1.8 at 300° (35% attenuation). For subject 2, the corresponding values were 1.77 at 80° and 1.26 at 280° (29% attenuation), and for subject 3, 2.6 at intervals of 60° and 160° and 1.28 at 320° (51% attenuation). The amplitudes of the net potentials were normalised to the average net potential of each subject and plotted against the phase interval between the two stimuli (fig 7). A tendency for the net potential to decrease between phase differences of 90° and 270° was observed.

**Subjects with specific lesions**

Six subjects with conductive hearing loss (eight affected ears) had absent VEMP to 145 dB SPL clicks and air conducted tone bursts of standard parameters on the affected sides. In contrast, VEMP to bone conducted tones of 115 dB/500 Hz/7 ms were present for in all affected ears.

Four subjects (five ears) with the Tullio phenomenon secondary to dehiscence of the superior semicircular canal had average thresholds of 107 dB SPL (62 dB NHL) to clicks, 90.4 dB SPL (82.4 dB HL), to air conducted tones, and 90.2 dB SPL (32.2 dB HL) to bone conducted tones, all significantly lower than those of normal subjects (p < 0.001). The average reduction in thresholds from normal values was 24.7, 23.6, and 10.1 dB for air conducted clicks and tones and bone conducted tones, respectively (fig 6).

We were able to observe Tullio patients with markedly reduced caloric responses binaurally (maximum SPV on stimulation of either side = 2°/s) as well as marked reduction of VOR to head impulses in the planes of all three semicircular canals on one side, with preservation of VEMP to clicks, air conducted tone bursts, and bone conducted tone bursts of standard parameters delivered to the right side, with corrected amplitudes of 0.97, 1.43, and 0.76 and raw amplitudes of 52.5, 44.9, and 45.1 µV, respectively. Upon stimulation of the left ear, VEMP to clicks were absent, and responses to air and bone conducted tones were markedly reduced, with corrected amplitudes of 0.37 and 0.42 and raw amplitudes of 23.8 and 67.0 µV, respectively.

**DISCUSSION**

Although head rotation and acceleration are the adequate physiological stimuli for the vestibular apparatus, non-mechanical stimuli such as loud sound, vibration, and galvanic currents activate primary vestibular afferents and have been used to evoke VEMP. Vestibular responses to sound have been attributed to stimulation of the saccule, which in other species such as fish and amphibians serves as a primary or secondary organ of hearing. Recordings from primary and secondary vestibular neurones in guinea pigs and cats in response to intense clicks or tones have shown increases in neural discharge. Using labelling techniques and responses to physiological stimuli, acoustically responsive afferents have been traced to the saccule. The vestibular apparatus is sensitive to vibration in amphibians and mammals. In...
ears tested. Similar optimum frequencies have been reported
frequency for bone conducted VEMP was 250 Hz for most of the
effectively in some subjects.

made for hearing. Bone conducted sound delivered through
activation of the ipsilateral vestibular apparatus. The larger
that “crossed” bone conducted VEMP do not depend upon
latencies compared with the ipsilateral response. The findings
(negative–positive responses) and also have earlier peak
latencies compared with the ipsilateral SCM and smaller ones with average peak
latencies occurring about 1 ms later contralaterally (p1 and n1 ranging between
11.9 and 16.5 ms and between 29.5 and 26.6 ms) recorded from the ipsilateral SCM and smaller ones with average peak
latencies compared with the ipsilateral response. The findings
in the subject with selective vestibular nerve section indicate that “crossed” bone conducted VEMP do not depend upon
activation of the ipsilateral vestibular apparatus. The larger
bone conducted VEMP recorded from the contralateral SCM in
two subjects further illustrate the vagaries of sound transmis-
sion by bone conduction. Similar observations have been
made for hearing. Bone conducted sound delivered through
the mastoid process has been shown, owing to the asymmetry
of skull thickness, to stimulate the contralateral cochlea more
effectively in some subjects. The optimum stimulus fre-
quency for bone conducted VEMP was 250 Hz for most of the
cars tested. Similar optimum frequencies have been reported
by Sheykholeslami et al. Differences between air and bone conducted
to the contralateral SCM are likely to relate to the different
filtering properties of bone and the middle ear as well as to
potential differences in the mechanism and specific site of
action of the two stimuli. As the B71 vibrator did not permit
delivery and accurate calibration of tones of less than 250 Hz
frequency, we were unable to define the tuning curve fully.

While VEMP to air conducted sound are thought to be of
saccular origin, the precise origin of the afferents responsible
for the bone conducted VEMP is not yet known. Previous
experiments which achieved phase cancellation of an air con-
ducted sound by a bone conducted sound demonstrated that the two stimuli activate cochlear receptors by similar
mechanisms. We have shown that the bone conducted VEMP is vestibular dependent and has similar latency and waveform
to the VEMP evoked by air tone bursts. Results obtained from
the patient with markedly attenuated canal function imply
that bone conducted VEMP arise from the otolith organs. Par-
tial cancellation of responses when air and bone conducted
tones were delivered out of phase is consistent with overlap in
the neural pathways stimulated by the two methods. We infer that the receptors responsible for bone conducted responses
are derived from the otoliths and in part, at least, from the saccule.

Stimulation over the mastoid yielded bone conducted VEMP more consistently compared with frontal and occipital
bone at the temporal bone anterior to the external acoustic
meatus. Audiometric studies comparing bone conduction thresholds over the frontal bones and mastoid report lower
thresholds over the mastoid. Studies in humans comparing
BAER latencies with the stimulus over the frontal, occipital,
and temporal bones have reported earlier wave V latencies to
temporal stimulation. Our optimum location for stimulus
delivery occurred almost always in one of the four locations
forming an inverted “L” shape posterior and superior to the
external acoustic meatus; other locations near the meatus
failed to show smaller responses. Sohmer and Freeman reported shorter
BAER latencies when the bone vibrator was placed anterior to
the external acoustic meatus over the thinnest part of the
temporal bone. We did not find bone conducted VEMP
amplitudes to be significantly larger anterior to the external
acoustic meatus. This may reflect the more posterior location
of the vestibular apparatus compared with the cochlea. Our
results indicate that effective stimulation can be delivered at
any one of the four optimal locations providing the bone con-
duction makes good mechanical contact. Symmetrical sites
should be used to minimise differences in amplitude between
sides.

The perceived loudness of sounds is a function of the mid-
dle ear, the cochlea, and the central neural pathways. The
standard measure of this property, for continuous sound, is
expressed as dB HL (hearing level) and the relation between
dB HL and dB SPL (sound pressure level) differs with
frequency. The HL reference is not appropriate when the coch-
lea is not the organ being stimulated by sound, as is the case
for VEMP. The reference levels for air and bone conducted
sound (0 dB) are defined differently. For sound in air, 0 dB SPL
is defined as a pressure (20 µPa), for bone conduction 0 dB SPL is
defined as a force (1 µN). The different reference levels pre-
vent direct comparison of air and bone conducted sound. If
force is used for comparison, 0 dB for air is substantially less
than 1 µN. At 1 kHz, 0 dB HL (for sound in air) is close to 0 dB
SPL, implying an extraordinary level of sensitivity, close to the
physical limits of detection. Contrasting with sound in air, 0
dB HL for continuous bone conducted sound is 42.5 dB higher
than the SPL reference for 1 kHz (and therefore approximately
130 times less sensitive). von Békésy argued that this
reduced sensitivity is a desirable characteristic that is in part a
consequence of the structure of the cochlea.

The stimulus threshold for air conducted VEMP was 114 dB
SPL = 106 dB HL, and that for bone conducted VEMP 97.5 dB
SPL = 30.5 dB HL at 250 Hz (using standard HL thresholds). The
difference between hearing thresholds and VEMP thresholds is much larger for air conducted sound than
for bone vibration. Bone vibration at a given perceptual inten-
sity is therefore a more effective vestibular stimulus than air
conducted sound, implying a relatively greater sensitivity of
the vestibular apparatus to bone conducted sound when com-
pared with the cochlea. Subjects with sound induced vestibular
symptoms—the Tullio phenomenon—have a low stimulus
threshold for VEMP to air conducted clicks, and this has been
attributed to an increased sensitivity of the vestibular appara-
tus to sound at the receptor level, as neural excitability has
been shown to be normal in these subjects. Bone conducted
VEMP thresholds, although still significantly lower than those
of normal subjects, were not as markedly reduced as the
thresholds of VEMP to air conducted clicks in the six subjects
with the Tullio phenomenon. A significant proportion of “bone
conduction” does in fact travel through the middle ear40 so
that some reduction in bone conducted VEMP thresholds
would therefore be expected. The vestibular receptors them-
selves appear to be normal; thus the component of vestibular
activation caused by a direct effect on the receptors by distor-
tional vibration and its inertial effects on the otoliths may be
unaltered, leading to lesser abnormalities than occur with air
conducted sound.
The clinical indications for the use of bone conducted VEMP are similar to those for taps, and they have a similar reproducibility, but they are more consistently present in normal subjects and can be calibrated. Bone conducted VEMP are therefore a suitable alternative to the tap VEMP which are more symmetrical, have a wider separation between normal thresholds and those of subjects with the Tullio phenomenon. All subjects with absent click evoked responses should be tested for VEMP to either bone conducted tones or taps to exclude conductive hearing loss as the cause. When compared with air conducted sound, larger bone conducted stimuli may be safely used, as they do not stimulate the cochlea as effectively. This technique may also be useful in studying older subjects with higher stimulus thresholds. Absent VEMP to both air and bone conducted sound suggest a lesion along the vestibulocochlear reflex pathway. Measurement of VEMP to transmastoid galvanic stimulation may yield useful information in this context, as this stimulus acts upon the terminal part of the primary vestibular afferents. The preservation of a response to galvanic stimulation when sound evoked responses are absent makes a lesion of the vestibular end organ most likely.

Conclusions
Bone conducted sound evokes VEMP that provide an additional measure of vestibular function, which is not confounded by conductive hearing loss. They complement information obtained from click VEMP and other techniques currently used in vestibular assessment.

ACKNOWLEDGEMENTS
This research was supported by a grant from the National Health and Medical Research Council of Australia. MSW received a medical research fellowship from the Garnett Passe and Rodney Williams Memorial Foundation during the period of this study. SMR translated excerpts of the work of Tullio. We thank Dr Toshihisa Murofushi for the technique of measuring bone conducted VEMP, Ms C Urban for translating the work of von Békésy, Dr G Colin-Thome for audiological advice, Mr P Bosloper for calibrating the bone conductor, and Mr Chi Sum Tsang for assistance with patient recruitment. We also acknowledge the expert assistance of Drs Phillip CREMER and Americo Migliaccio in testing three dimensional VOR of two subjects with specific lesions.

Remission of progressive multifocal leucoencephalopathy in SLE after treatment with cidofovir: a 4 year follow up

Progressive multifocal leucoencephalopathy (PML) is an opportunistic infection caused by human polyomaviruses such as the JC virus. It usually occurs as a severe complication of immunosuppression in patients with primary disorders of the immune system or secondary impairment of immune function, for example, after iatrogenic states of immunosuppression. PML usually takes a rapidly progressive course and advances to death within 1 to 18 months. Today, PML is mainly seen in AIDS, while previously it was typically found in patients with granulomatous, neoplastic, or infectious diseases. In granulomatous diseases particularly, PML is thought to occur as a result of iatrogenic states of immunosuppression, but it is also seen in patients aggressively treated with immunosuppressive therapy for systemic lupus erythematosus (SLE). PML progresses to death in most of these patients even after withdrawing immunosuppressive therapy. Therefore additional therapy, aimed at supporting a more rapid restoration of immune function has warranted.

Case report

We report a 40 year old woman diagnosed with SLE at the age of 20 years, based on four American College of Rheumatology criteria (erythema, arthritis, elevated antinuclear antibodies, and anti-dsDNA antibodies). Owing to neuropsychiatric lupus (the patient had experienced several psychotic episodes) with suspected vasculitic changes on cerebral magnetic resonance imaging (MRI), the patient had undergone 12 cycles of cyclophosphamide pulse therapy in 1995/96 followed by immunosuppressive treatment with mycophenolate mofetil in 1998, and azathioprine in 1999. Follow up cerebral MRI scans at that time were normal.

In January 2001, she again developed psychotic episodes and an initially mild ataxia. She had repeatedly been put on low doses of corticoids but on no other immunosuppressive therapy during the previous 2 years. MRI revealed a lesion in the left cerebellum, which was hyperintense on T2 and hypointense on T1 weighted images. No lesions were seen in the cerebral hemispheres. Central nervous system manifestation of SLE was suspected, although the patient revealed only moderate signs of SLE activity (elevated anti-dsDNA antibodies, slightly decreased complement levels C3c and C4, increased erythrocyte sedimentation rate, but normal C reactive protein). There were no signs of severe immunosuppression; laboratory data showed normal levels of immunoglobulins and only slightly decreased lymphocytes, especially CD8+ T lymphocytes. The patient received two pulses of cyclophosphamide and high doses of corticosteroids to reduce the presumed cerebral SLE activity. In addition, she received antipsychotic medication.

While the psychosis was readily controlled by this treatment, the patient deteriorated neurologically. She developed a severe, disabling, rapidly progressive, left sided hemi-ataxia, and was unable to walk. A control MRI of the brain in February 2001 revealed a progression of the lesion in the left cerebellum and a new lesion in the middle cerebellar peduncle. The lesions again presented as hyperintense on T2 and hypointense on T1 weighted images (fig 1A). Owing to the neurological deterioration after initiation of immunosuppression and the presentation of the lesions on MRI, PML was considered as a differential diagnosis. PCR revealed JC virus DNA in the cerebrospinal fluid (CSF). As cerebral SLE and PML require an intense but divergent therapy, a brain biopsy was obtained from the cerebellar lesion. Histopathology confirmed the diagnosis of PML. HIV tests were negative, T cell counts were normal, and signs of malignancy were lacking. Immunosuppression was discontinued. Because PML is usually lethal in patients with SLE even after omission of immunosuppression, we considered options for an active antiviral therapy. There was evidence from several reports in AIDS patients that cidofovir, an inhibitor of viral DNA polymerase, may reduce the size of PML lesions and thus prolong survival.

Lacking therapeutic alternatives we therefore administered intravenous cidofovir (5 mg/kg body weight) at initially bi-weekly intervals, after obtaining informed consent. After the third and fourth cycle, the patient improved dramatically. She was able to walk again and only showed a mild residual ataxia. MRI revealed reduction of the lesions in the cerebellum and middle cerebellar peduncle with no new sites of active disease (fig 1B). PCR for JC virus DNA in the CSF was now negative. The treatment with cidofovir was continued with longer intervals (8–12 weeks). The therapy was generally well tolerated. After the fifth cycle, mildly increased creatinine levels were found. After one cycle with 4 mg cidofovir/kg body weight, kidney function was quickly normalised and the following cycles could be administered at the initial dosage. Fourteen months after initiation of the treatment, the patient had completed the 10th cycle of therapy with no signs of disease activity. MRI scans of the brain showed further regression of the lesion with no signs of progression.
active inflammation (not shown), and cidofovir treatment was discontinued. At present, 4 years follow up after the first treatment and 2.5 years after the last cycle of cidofovir, the patient still shows no signs of disease activity. CSF PCR for JC virus DNA remains negative, and a recent MRI scan of the brain was unchanged (fig 1C). As of March 2005, the patient lives at home, is able to walk, and is independent.

Discussion

We report a patient with SLE who survived PML after treatment with cidofovir and discontinuation of immunosuppression. First evidence for possible efficacy of cidofovir in the treatment of PML in a patient with SLE was presented in a case report. Discontinuation of immunosuppression and treatment with cidofovir resulted in reversal of JC virus positivity and stabilisation of MRI lesions. However, the patient died due to serious kidney failure.

It remains unclear whether the improvement in both patients was induced or supported by cidofovir or whether it could have been acquired by discontinuation of immunosuppression alone. However, patients with PML in SLE usually die due to disseminated immunosuppression, which suggests a predisposition of patients with SLE to PML that may not be explained by their immunosuppression alone.

We conclude that cidofovir should be offered to SLE patients developing PML due to immunosuppression in addition to withdrawal of immunosuppressive therapy, as death is likely without antiviral therapy. Cidofovir may be effective against PML caused by non-AIDS related states of immunosuppression.

Dramatic improvement in non-AIDS related progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a rare disorder occurring when a strain of papovavirus (JC virus) infects the central nervous system. It results in a generally quick and fatal outcome. It is associated with cell mediated immune deficiency, but some few cases were reported in immunocompetent hosts. Since 1981, it has been commonly associated with AIDS. In AIDS related PML, long term survival without real neurological improvement has been reported in patients treated with highly active antiretroviral therapy (HAART). Few cases of improvement with cidofovir or aracytine have been described in AIDS related or non-AIDS related PML, but in larger trials in AIDS related PML, no clinical benefit was found. As a whole, the treatment of this progressive demyelinating disease remains controversial, and in particular in the rare cases of non-AIDS related PML. We describe a patient with an underlying haematological disease, without clear cut immune cell deficiency, who developed rapidly progressive PML. The patient showed clinical, virological, and imaging improvement when treated with an association of intravenous and intrathecal cytarabine and cidofovir.

A 48 year old man presented with progressive multiple lymphadenopathies, hepatosplenomegaly, weight loss, and blood cell count abnormalities. Fine needle aspiration cytology of lymphadenopathy diagnosed marginal zone B cell lymphoma. There was also bone marrow and blood proliferation. A few weeks after the diagnosis, the patient noticed rotatory vertigo and visual problems suggestive of a right homonymous hemianopia. Because of dissemination and the large tumour mass, chemotherapy (CHOP: cyclophosphamide, doxorubicin, vincristine and prednisone) was started one month after the onset of neurological symptoms. Following the first course of chemotherapy, his neurological symptoms worsened, and language disorders appeared. No real immunodeficiency was shown—the absolute CD4+ count was 549/mm³ (normal 858–1250/mm³), and there was discrete hypogammaglobulinaemia (4.6 g/L; normal 5–12). The patient was HIV and HTLV1 seronegative. Cerebral magnetic resonance imaging showed a non-contrast-enhancing lesion in the left occipital white matter (fig 1A).

Cerebrospinal fluid (CSF) analysis was normal apart from a moderate increase in CSF protein (0.7 g/L). Susception of PML was confirmed by a positive polymerase chain reaction (PCR) for JC virus DNA. Chemotherapy was discontinued and treatment was changed to cidofovir intravenous twice weekly and aracytine intrathecal twice weekly. As the result of immunosuppressive therapy the patient was still in good condition, and neurological symptoms worsened rapidly and the patient developed a right hemiplegia, global aphasia, alexia and agraphia, apraxia, and cortical blindness concurrently with MRI deterioration (fig 1B).

Three months after his first symptoms, treatment was started with intravenous aracytine 2 mg/kg/d for five days every three weeks, combined with intrathecal aracytine (30 mg) weekly and intravenous cidofovir 5 mg/kg/d once every two weeks. The main adverse effect of this treatment was grade IV bone marrow toxicity, inducing spacing in the rhythm of treatment administration. One week after treatment onset, the patient stabilised and after one month began improving. After three months, he had recovered completely from his hemiplegia, and had significant improvement in his aphasia and cortical blindness. Right hemianopia and minor alexia without agraphia persisted. This dramatic improvement was confirmed by cerebral imaging, by the absence of JC virus DNA detection in CSF, and by a specific response of CD4+ T cells against JC virus. We decided to continue subcutaneous aracytine 2 mg/kg/d for five days monthly and intravenous cidofovir twice weekly. Fifteen months after treatment onset, the patient was aphasia free and cerebral MRI continued to improve (fig 1C). Lymphoma tumour burden did not clearly change during the treatment.

Comment

We report the favourable outcome of a patient with non-AIDS-related PML treated with a combination of intravenous and intrathecal aracytine and cidofovir. As the patient was not immunocompromised and had not received immunosuppressive treatment at PML onset, risk factors for the occurrence of PML are unclear. Treatment led to a rapid clinical and radiological improvement which was long lasting despite treatment delay and the patient’s worrying clinical condition at treatment onset. Dose and administration schedules of cytarabine and cidofovir were derived from previous reports, suggesting individual beneficial effects of these drugs. To our knowledge, these drugs have not been used in combination before. In comparison with previous reports, the present case suggests a more rapid and prolonged effect of this therapeutic combination than with either aracytine or cidofovir treatment alone. This efficacy may be explained by a synergy between the drugs and by their different routes of administration. We thought that the improvement in our patient was related to the treatment because there was a temporal link with treatment onset and because of the radiological findings. In cases of PML stabilising without specific treatment have usually been associated with an inflammatory response to the virus, indicated by contrast enhancement on imaging). The main limitation factor of this case was bone marrow toxicity. During the periods of immune deficiency, the patient’s neurological condition did not deteriorate, suggesting that PML occurrence in this patient was linked to a qualitative defect of cells rather than to their absolute count. Immunological studies have shown that JCV specific CD4-T cell responses play a
major role in the control of PML development; for example, in one study the specific T cell response was demonstrated in a series of 14 patients before treatment, whereas nine of 10 survivors recovered specific immunity. Our patient thus probably had no specific T cell response against JCV before treatment, but recovered a moderate but significant response while on treatment, possibly explaining PML regression. Such a restoration of T cell response can be achieved by HAART in AIDS. This observation suggests that the combination of aracrine and cidofovir could have had a similar action in restoring a specific T cell response against JCV in our patient. A direct effect of these nucleoside analogues against JC virus DNA may also explain the rapid clinical and radiological improvement in our patient. Despite its substantial bone marrow toxicity, this observation suggests that the new association of intrathecal and intravenous aracrine with intravenous cidofovir could be useful in patients with PML, particularly those with an underlying haematological disease. It is worth noting that bone marrow toxicity did not lead to deterioration of the neurological status of the patient, supporting the view that a specific effect in CD4 function is more important than the absolute CD4 count. The dramatic improvement observed in our patient warrants further prospective studies testing this drug combination.

Diaphragmatic paralysis and respiratory failure as a complication of Lyme disease

There have been five recorded cases of diaphragmatic paralysis as a complication of neuroborreliosis.1 2 Here we report another case of Lyme meningocardiitis, caused by an identified tick, leading to bilateral diaphragmatic paralysis with an abbreviated course on treatment.

Case report

A 59 year old female presented with a recent history of abdominal pain and falls because of a weakness in her right leg. She had been complaining of flu-like symptoms with twitches in her back and pain in her right side for a month. She gave a history of recently having been bitten by ticks whilst gardening. There was no history of any recent rash. On the day of presentation, she complained of a mild cough, reduced appetite, abdominal distension, constipation, and dysuria. She was a lifelong smoker but was generally healthy.

At presentation her blood pressure was 126/70 mm Hg. There was no epigastric tenderness. She had bruising on her right leg that she associated with the falls.

The chest radiograph on admission was unremarkable. Abdominal x ray showed dilated loops of small bowel and a loaded colon. Her only blood abnormality was hyponatraemia at 121 mmol/l. She was admitted for further investigations.

On day 3 of admission she became increasingly short of breath and on examination had decreased bibasal air entry. On day 4 her respiratory rate was 25/min and arterial blood gases (ABG) demonstrated hypoxaemia but adequate ventilation with pH 7.51, Po2 7.6 kPa, and Pco2 4.7 kPa. Her chest radiograph showed left basal changes. On day 5 her Pco2 had risen to 6.8; she was admitted to the intensive care unit and non-invasive ventilatory support was commenced. She had a decreased inspiratory pressure and a decreased vital capacity. She was noted to have absent gag reflex and poor swallowing and on day 6 was intubated to protect against aspiration pneumonia. The patient remained fully conscious and co-operative, easily triggered the ventilator but requiring significant inspiratory pressure support of 20 cm H2O.

Neurological examination demonstrated right hip and knee extensor weakness (2/5), absent right knee jerk, and a loss of sensation on her left lateral thigh. Because she lived in a known endemic area we thought about Lyme disease, but we also considered differential diagnoses such as Guillain-Barre syndrome, listeriosis, and acute polymyalitis. We commenced treatment with doxycycline whilst awaiting the results of further investigations. Around this time the patient indicated a small black lesion on her upper abdomen that was removed and on closer examination was identified as tick mouthparts (fig 1).
Given her smoking history and persistent hyponatraemia, a chest computerised tomography was performed which showed only left lower lobe collapse and a small left pleural effusion. Bronchoscopy was unremarkable. Chest ultrasound screening showed only minimal movement of both diaphragms.

Cerebrospinal fluid analysis (CSF) demonstrated a white cell count 181 cells/mm³ (100% mononuclear), red cell count 22 cells/mm³, glucose 2.3 mmol/l (serum glucose 4.1 mmol/l), protein 2.3 g/l and lactate 1.1 mmol/l. Immunoglobulin M and immunoglobulin G antibodies to Borrelia burgdorferi were not carried out. Immunoglobulin M and immunoglobulin G antibodies to *Borrelia burgdorferi* were detected in serum, and at this point intravenous ceftriaxone (2 g for 14 days) was commenced.

Over the next 7 days her strength increased and a repeat ultrasound of the diaphragm on day 16 of admission showed marked improvement with the right dome moving normally and some residual left sided weakness associated with overlying lung consolidation.

The patient was weaned from the ventilator and extubated following a total of 22 days of respiratory support. She underwent intensive physiotherapy and has made an uneventful recovery. One year later she complained of mild shortness of breath on lying flat with an exercise tolerance of 1 mile on the flat. On examination she had hyperaesthesia in her right leg with slightly brisk knee reflexes (previously absent right knee jerk). She had persistent bilateral diaphragmatic paralysis demonstrated on chest ultrasound screening. Pulmonary function tests showed a 40% reduction between erect and supine vital capacity measurements.

**Discussion**

The first case of diaphragmatic paralysis as a complication of Lyme disease was reported in 1986: a 73 year old male, treated with ampicillin and netilmicin, who required ventilation for 5 months and then died after receiving treatment for a pulmonary embo-

In all previous cases of diaphragmatic palsy as a complication of Lyme disease, either the patient reported dyspnoea or hypoxia was noted on ABC. The diagnosis of phrenic nerve palsy was made by the following methods: hemidiaphragmatic elevation, fluoroscopic screening of diaphragmatic movements, or electrical stimulation of phrenic nerves.\(^1\)\(^2\)\(^3\)\(^4\)\(^5\) Our patient had a lymphocytic meningitis with sensory and motor neuropathies including bilateral phrenic nerve palsies. Diaphragmatic paralysis due to Lyme disease was diagnosed on the basis of clinical features, chest ultrasonography, the presence of the tick head, and serology indicating a recent infection with *B burgdorferi* as well as a rapid response to antibiotic therapy.

The clinical diagnosis of Lyme disease may be supported by serologic testing. *B burgdorferi* antibody tests may be negative in early infection, but patients are usually seropositive at or shortly after presenting with neurological symptoms. In some patients, antibodies against *B burgdorferi* may be detectable in CSF slightly earlier than serum. Culture and *B burgdorferi* desoxyribonucleic acid detection using polymerase chain reaction may also be used but were not in our case.

The three patients reported in the literature with respiratory failure caused by neuroborreliosis were ventilated for 3 months, 1 month, and 13 months, respectively, whilst our patient required ventilation for only 22 days.\(^6\)\(^7\)\(^8\)\(^9\)\(^10\) We speculate that early recognition of the possibility of Lyme disease and appropriate treatment shortened our patient’s acute illness.

In conclusion, it is important to consider Lyme disease in the differential diagnosis of acute respiratory failure – with or without myasthenia migrans.

**Benign paroxysmal positional vertigo (BPPV) predominantly affects the right labyrinth**

We read with great interest the article ‘Benign paroxysmal positional vertigo predominantly affects the right labyrinth’, by M von Bреверт et al., which prompted us to review our data of the last 10 years (1995–2004).

A total of 661 patients, referred to the ear, nose, and throat department or to the neurology department, were diagnosed as having benign paroxysmal positional vertigo (BPPV) in its various forms. The pathology was located in the posterior canal in 477 patients, in the horizontal canal in 142, and in the anterior canal in 22. Multiple canals were affected in 20 patients (table 1).

The right ear was 1.50 times more frequently involved than the left. The predominance of the right ear was seen in all types of BPPV (table 1).

Hence, our data confirm the preponderance of right sided BPPV. The predilection of right sided BPPV was seen in all variants. Horizontal canal BPPV was observed in 22%, confirming our previous data.\(^1\)\(^2\)\(^3\)\(^4\)\(^5\) The apogeotropic form should not be considered as a rarity as it contributes to 23% of horizontal canal BPPV in our series and 38% in the series of Casani et al.\(^1\)

Aciclovir induced posterior leucoencephalopathy

Aciclovir is an extremely effective agent for the treatment of herpes simplex encephalitis and varicella–zoster infections in immuno-compromised individuals.1 Encephalopathy induced by aciclovir is an infrequent but well recognised adverse effect of aciclovir.2 The predisposing factors to aciclovir induced encephalopathy (AIE) include age, acute or chronic renal failure, and other neurotoxic drugs. Tremors (40–58%), disorientation (40–90%), agitation (22–30%), hallucinations (25%), and delirium (23%) are common presentations of AIE, whereas seizures (10%), cerebellar ataxia (11%), sensory symptoms (9%), speech disorders (9%), fever (3%), and cranial nerve palsies (0%) are much less frequent.2 The supportive diagnostic criteria for AIE include a temporal association between the symptoms and aciclovir use, as well as acellular cerebrospinal fluid (CSF) in cases without herpes simplex or varicella–zoster encephalitis. In the majority of cases symptoms develop within 72 hours of starting aciclovir treatment, although up to 120 days has been reported.4 The clinical recovery may take several days (five days in 57% of cases) following discontinuation of aciclovir.3 The EEG typically shows diffuse slow wave activity rather than focal abnormalities.2

The radiological features are not well described in AIE. Case reports have identified multifocal white matter signal abnormalities involving the cerebellum, pons, and periventricular region as well as evidence of vascular encephalopathy on MRI.2 3 We report a case of AIE with MRI features consistent with posterior leucoencephalopathy with clinical and radiological improvement following the discontinuation of aciclovir, along with raised serum and CSF concentrations of aciclovir and 9-carboxymethoxymethylguanine (CMMG), the main metabolite of aciclovir.

Case report

A 47 year old women with a 15 month history of cANCA5 glomerulonephritis and chronic renal failure, and varicella–zoster virus, cryptococcal antigen, varicella–zoster virus, cryptococcal antigen, and JC virus. An EEG showed excessive slow wave activity. Magnetic resonance imaging (MRI) showed symmetrical posterior white matter changes predominantly in the occipital and parietal lobes (fig 1A and 1B) without evidence of venous sinus thrombosis, gadolinium enhancement, or matched defects in diffusion weighted images.

On admission, azathioprine was stopped and intravenous methylprednisolone (500 mg/day for three days) was started for presumed CNS vasculitis. There was no improvement 72 hours after this treatment and after eight days of aciclovir. Aciclovir was discontinued when AIE was suspected, and peritoneal dialysis was maintained. Within 48 hours of discontinuation of aciclovir, the GCS improved (eye score 3, motor score 6, verbal score 3) and neurological examination showed bilateral upper limb postural tremor, which resolved over 24 hours. The Addenbrooke’s score was 77/100. Repeat MRI (fig 1C, 1D) showed a significant improvement. Analysis of aciclovir and CMMG levels in the serum and CSF showed high values, at levels generally associated with neurotoxicity.3 The serum aciclovir and CMMG concentrations were, respectively, as follows:

- 5 days post-aciclovir initiation: 34.9 μmol/l and 91.7 μmol/l;
- 6 days post-aciclovir: 35.4 μmol/l and 148.5 μmol/l;
- 7 days post-aciclovir: 17.2 μmol/l and 141 μmol/l.

The CSF aciclovir and CMMG concentrations four days post-aciclovir initiation were, respectively, 5.99 μmol/l and 2.25 μmol/l (CMMG levels are not detectable in CSF unless there is neurotoxicity (Hellidén A, submitted for publication)), supporting a diagnosis of AIE.3

Comment

The clinical presentation of our patient, her rapid recovery, and the CSF and EEG findings are characteristic of cases without herpes simplex or varicella–zoster encephalitis.4 5 The lack of significantly raised blood pressure or papilloedema excludes hypertensive posterior leucoencephalopathy. ANCA vasculitis causing posterior leucoencephalopathy has been reported but only in the presence of severe hypertension. AIE, an infrequent but well recognised adverse effect of aciclovir, has until now been diagnosed.

Figure 1 Fluid attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) of the brain done five days after initiation of aciclovir treatment, showing features consistent with posterior leucoencephalopathy (panels A and B). Repeat MRI five days after discontinuation of aciclovir showed a marked improvement (panels C and D).

Aciclovir induced posterior leucoencephalopathy

Aciclovir is an extremely effective agent for the treatment of herpes simplex encephalitis and varicella–zoster infections in immuno-compromised individuals.1 Encephalopathy induced by aciclovir is an infrequent but well recognised adverse effect of aciclovir.2 The predisposing factors to aciclovir induced encephalopathy (AIE) include age, acute or chronic renal failure, and other neurotoxic drugs. Tremors (40–58%), disorientation (40–90%), agitation (22–30%), hallucinations (25%), and delirium (23%) are common presentations of AIE, whereas seizures (10%), cerebellar ataxia (11%), sensory symptoms (9%), speech disorders (9%), fever (3%), and cranial nerve palsies (0%) are much less frequent.2 The supportive diagnostic criteria for AIE include a temporal association between the symptoms and aciclovir use, as well as acellular cerebrospinal fluid (CSF) in cases without herpes simplex or varicella–zoster encephalitis. In the majority of cases symptoms develop within 72 hours of starting aciclovir treatment, although up to 120 days has been reported.3 The clinical recovery may take several days (five days in 57% of cases) following discontinuation of aciclovir.3 The EEG typically shows diffuse slow wave activity rather than focal abnormalities.2

The radiological features are not well described in AIE. Case reports have identified multifocal white matter signal abnormalities involving the cerebellum, pons, and periventricular region as well as evidence of vascular encephalopathy on MRI.2 3 We report a case of AIE with MRI features consistent with posterior leucoencephalopathy with clinical and radiological improvement following the discontinuation of aciclovir, along with raised serum and CSF concentrations of aciclovir and 9-carboxymethoxymethylguanine (CMMG), the main metabolite of aciclovir.

Case report

A 47 year old women with a 15 month history of cANCA5 glomerulonephritis and chronic renal failure, and varicella–zoster virus, cryptococcal antigen, varicella–zoster virus, cryptococcal antigen, and JC virus. An EEG showed excessive slow wave activity. Magnetic resonance imaging (MRI) showed symmetrical posterior white matter changes predominantly in the occipital and parietal lobes (fig 1A and 1B) without evidence of venous sinus thrombosis, gadolinium enhancement, or matched defects in diffusion weighted images.

On admission, azathioprine was stopped and intravenous methylprednisolone (500 mg/day for three days) was started for presumed CNS vasculitis. There was no improvement 72 hours after this treatment and after eight days of aciclovir. Aciclovir was discontinued when AIE was suspected, and peritoneal dialysis was maintained. Within 48 hours of discontinuation of aciclovir, the GCS improved (eye score 3, motor score 6, verbal score 3) and neurological examination showed bilateral upper limb postural tremor, which resolved over 24 hours. The Addenbrooke’s score was 77/100. Repeat MRI (fig 1C, 1D) showed a significant improvement. Analysis of aciclovir and CMMG levels in the serum and CSF showed high values, at levels generally associated with neurotoxicity.3 The serum aciclovir and CMMG concentrations were, respectively, as follows:

- 5 days post-aciclovir initiation: 34.9 μmol/l and 91.7 μmol/l;
- 6 days post-aciclovir: 35.4 μmol/l and 148.5 μmol/l;
- 7 days post-aciclovir: 17.2 μmol/l and 141 μmol/l.

The CSF aciclovir and CMMG concentrations four days post-aciclovir initiation were, respectively, 5.99 μmol/l and 2.25 μmol/l (CMMG levels are not detectable in CSF unless there is neurotoxicity (Hellidén A, submitted for publication)), supporting a diagnosis of AIE.3

Comment

The clinical presentation of our patient, her rapid recovery, and the CSF and EEG findings are characteristic of cases without herpes simplex or varicella–zoster encephalitis.4 5 The lack of significantly raised blood pressure or papilloedema excludes hypertensive posterior leucoencephalopathy. ANCA vasculitis causing posterior leucoencephalopathy has been reported but only in the presence of severe hypertension. AIE, an infrequent but well recognised adverse effect of aciclovir, has until now been diagnosed.

Figure 1 Fluid attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) of the brain done five days after initiation of aciclovir treatment, showing features consistent with posterior leucoencephalopathy (panels A and B). Repeat MRI five days after discontinuation of aciclovir showed a marked improvement (panels C and D).

www.jnnp.com
mainly on clinical features. Factors predisposing to AIE include age, acute or chronic renal failure, and other neurotoxic drugs. The diagnosis is facilitated by analysis of aciclovir and CMMG in serum and CSF. In cases with renal failure, the half life of aciclovir extends from 3 to 20 hours and as a result aciclovir is metabolised to CMMG by alcohol and aldehyde dehydrogenases.

Normal memory and no confabulation after extensive damage to the orbitofrontal cortex

Subarachnoid haemorrhage caused by the rupture of an anterior communicating artery (ACoA) aneurysm is often followed by amnesia, confabulation, and personality change including social decision making. However, the regions responsible for each symptom have not been determined conclusively. We describe a patient who showed personality change, but neither memory impairment nor confabulation, after extensive damage to the bilateral orbitofrontal cortex, demonstrating by magnetic resonance imaging, proving that the destruction of the medial orbitofrontal cortex alone cannot cause amnesia and confabulation.

Case report

The patient was a 45 year old, right handed man with a 16th grade education. He was not an anesthetic person and worked hard as a manager before the onset. His past medical history was unremarkable and he had no medication. He had sudden onset of headache, became unconscious, and was admitted to an emergency hospital. Brain computed tomography showed a subarachnoid haemorrhage in the cisterns around the brainstem, longitudinal cerebral fissure, and bilateral Sylvian fissure caused by a ruptured aneurysm of the ACoA. On the same day, he underwent an operation to repair the ruptured aneurysm. There were slight brain oedema and vasospasm (four to 10 days). He did not become delirious, agitated, or suspicious. He had 200 mg of phenytion each day to prevent secondary seizures. His family noted that he showed mild anterograde amnesia, which improved over two months, but no retrograde amnesia.

The patient was discharged home after three months. He began working again as a manager at his company, but could not do his job as well as before the onset. Twenty months after the onset, he was admitted to our hospital for assessment of his problem.

On admission, the patient was fully alert and oriented. General physical and neurological examinations were unremarkable. During his stay in hospital, he had no problems communicating with others, kept his appointments and could find his way around the hospital. His family and his superior at his company reported that his personality had changed since the onset of his illness (in terms of lack of concern for others including his family, his appearance, and his future; the loss of spontaneity, initiative, and self motivation; disinhibition; and rigidity of thought) generally agreed in the literature to be the result of dysfunction of the frontal lobe, particularly the orbitofrontal cortex. Importantly, the patient showed no memory deficit. Damage to the basal forebrain without damage to the frontal lobe causes amnesia. With regard to the orbitofrontal cortex, it has been argued that destruction of this region is not necessary for the development of amnesia or basic cognitive functions. However, there has so far been no conclusive evidence as to whether or not damage to the orbitofrontal cortex alone does not result in amnesia and therefore strengthens the notion that the basal forebrain is one of the crucial sites for human memory.

It should be noted that the assessment of memory in our present study is based on standardised tests. This means that memory that is not measurable using these standardised tests (for example, temporal context memory) may be related to the function of the orbitofrontal cortex. We cannot draw a strong conclusion regarding frontal lobe function, because we did not use tests sensitive to damage to the ventromedial prefrontal cortex (for example, the Iowa Gambling Task). The patient showed no confabulation. Damage to the orbitofrontal lobe alone might not be sufficient for confabulation to be
manifest. In one study, confabulation was seen in amnestic but not in non-amnestic patients with rupture of the ACoA and frontal lobe lesions, and in another study of amnestic patients with rupture of the ACoA, only those with frontal lobe lesions showed confabulation, suggesting that both frontal lobe lesions and amnesia are necessary for the development of confabulation. In contrast, a patient with confabulation and amnesia after damage to the basal forebrain but without frontal lobe damage has been reported. Further studies involving comprehensive neuropsychological and magnetic resonance imaging examination are needed to determine whether both frontal and basal forebrain involvement or basal forebrain involvement alone is required for the manifestation of confabulation.

Figure 1  (A) Sagittal and (B) coronal T2 weighted magnetic resonance images showing extensive lesions in the bilateral orbitofrontal cortex. The core structures of the basal forebrain (medial septal nucleus, vertical and horizontal limb nuclei of Broca’s diagonal band, and nucleus basalis of Meynert) were not damaged. In the sagittal sections, the images in the upper row show the right hemisphere and those in the lower row show the left hemisphere. In each row, the first, second, and third images are 15 mm, 10 mm, and 5 mm away from the longitudinal cerebral fissure, respectively. In the coronal sections, the left side of the image corresponds to the right side of the brain. In the upper row, the first, second, and third images are 0 mm, 5 mm, and 10 mm rostral from the anterior commissure. In the lower row, the first, second, and third images are 20 mm, 30 mm, and 50 mm rostral from the anterior commissure.

Adult onset SSPE: experiences in West Yorkshire over a 12 month period

Subacute sclerosing panencephalitis (SSPE) is a rare delayed complication of measles virus infection in infancy. It is characterised by behavioural changes, myoclonus, cognitive impairment, visual disturbance, pyramidal and extrapyramidal signs, and ultimately coma leading to death. Typically, SSPE presents in childhood or early adolescence, but adult onset cases are recognised. Widespread measles immunisation in the UK has led to a dramatic fall in the incidence of SSPE in children, leading to the disease almost becoming extinct. However, a latent disease pool remains and cases may still come to the attention of adult neurologists, as borne out by our recent experience in West Yorkshire.

Case histories
An 18 year old man gave a three week history of blinking episodes lasting approximately one second, associated with a brief head jerk. These were not present in sleep. Examination revealed myoclonic jerks involving the neck associated with blinking. Initial electroencephalograms (EEGs), blood tests, and a magnetic resonance imaging scan were normal. Several anticonvulsant medications failed to suppress the jerks, which by four weeks had spread to the legs, causing unsteadiness. The mini mental test examination score at this stage was 26 of 30. He began to deteriorate rapidly, with disorientation, blunted affect, dystonic posturing of the left arm, bradykinesia, and rigidity. Cerebrospinal fluid (CSF) was sent for analysis of 14-3-3 proteins, which were negative. A further EEG, nine weeks after onset, demonstrated high voltage periodic complexes occurring every 10 seconds, consistent with SSPE. CSF and serum measles titres were raised at 35110 mIU/ml and 152930 mIU/ml, respectively. The CSF to serum albumin ratio was 1:300, consistent with intrathecal antibody synthesis. There was no past history of measles, although he had received MMR (measles mumps rubella) immunisation at age 9. Oral inosiplex (isoprinosine) and an Ommaya reservoir was inserted to its removal. His condition plateaued and he was maintained on inosiplex alone. Eventually, he was discharged home in a dependent state.
A 25 year old woman presented to her general practitioner complaining of impaired concentration, mood swings, disturbed sleep, and memory loss. One month later, she had noticed a fine tremor in both hands and occasional spasms affecting her right foot. Her concentration was worse and she mentioned word finding difficulties. She also had a tremor in her left hand and fall. She was seen by a psychiatrist and somatisation was initially suspected. Later, she was referred to a neurologist. She noted that she had been acting oddly—for example, being found by her mother in a bath of cold water. Neurological examination was normal except for a mini mental test examination score of 20 of 30 with a child-like effect and stilted speech. A magnetic resonance imaging scan was unremarkable. She continued to deteriorate, developing right sided myoclonus. By this stage, she was unable to perform simple tasks, such as washing, and was aware of clashing sensations all over her body. Six months after her first presentation she had an EEG. This revealed repetitive complexes occurring every four to six seconds, often associated with a myoclonic jerk and consistent with SSPE. CSF analysis confirmed oligoclonal bands not present in the serum, which were positive for measles antibody antigen by immunoblotting. She had contracted measles at age 11 months. She started on oral piracetam and inosiplex, along with subcutaneous interferon alpha-2b. She became bed bound with quadriparesis, dysarthria, and diffuse hyperalgesia. Her treatment was changed to intravenous interferon alpha-2a administered via an Ommaya reservoir. She received continuous infusions of midazolam and dexamphetamine for symptom control, and nasogastric feeding was started. Her condition subsequently stabilised and she was discharged to a children’s hospice.

Discussion

The estimated incidence of SSPE each year in developed nations is < 1/10 million of the population under the age of 20. The occurrence of two adult cases in the small region of West Yorkshire (population two million) within a few months of one another is remarkable. Although probably a chance finding, our experience emphasises the need for continued surveillance in populations where measles is no longer endemic. In theory more adult onset SSPE cases could present to neurologists in the future. This is because slow central nervous system spread of the virus over many years leaves open the potential for SSPE to present in later life, decades after population eradication of measles. In addition, routine immunisation has led to a shift in the incidence of measles towards unprotected children age < 1, who are at a higher relative risk of developing SSPE in later life after a longer incubation period. Subsequently, there has been an increase in the number of measles outbreaks after a decline in the uptake of the combined MMR immunisation because of safety fears. In our patients, SSPE was not initially suspected by their general practitioner. Enquiring about measles in childhood may have been helpful in case 2, but not case 1, because infection in infancy was probably subclinical. In this patient the lack of typical findings at initial EEGs led to further delay, and instead we considered variant Creutzfeldt Jakob disease as a possibility. Patient 2 presented with early cognitive and behavioural changes. Initially, patients may come to the attention of other specialties with non-specific or psychiatric symptoms. It was only subsequent worsening of the patient’s mental state associated with the development of unilateral myoclonic jerks that prompted further investigation, including EEG.

There is no curative treatment for SSPE. Trials have been complicated by variable natural history and spontaneous long remissions of the disease, although it is eventually fatal (median survival, three years). One study demonstrated similar response rates among patients randomised to inosiplex, with or without intraventricular interferon alpha-2b treatment for six months (35% v 34%).

However, these figures were substantially higher than historical remission rates of between 5% and 10%. In our hands, intraventricular interferon was associated with initial worsening of encephalopathy and pronounced hyperpyrexia, possibly the result of chemically induced meningitis, and resolving infection was a further complication. In both patients, disease appeared eventually to stabilise after antiviral treatment, particularly in patient 1, in whom rapid progression at onset was suggestive of fulminant SSPE, usually fatal within three months.

Prevention seems to be the best approach, with mass immunisation leading to a drastic reduction in reported cases of measles and associated complications. However, our experience suggests that measles in adults should not be forgotten. Clinicians should remain vigilant for this devastating disease.

LATERALITY OF SYMPTOMS IN PATIENTS ADMITTED TO A STROKE UNIT WHO HAD A DIAGNOSIS OF PSYCHIATRIC DISORDER

Some psychiatric conditions produce symptoms that can mimic an acute neurological disease, including stroke. In several studies, such symptoms seemed to be more common on the left side of the body. The predominant processing of emotional information by the right hemisphere offers a hypothetical explanation for this finding.

We reviewed the discharge summaries of patients who were admitted to a stroke unit during the period May 1996 to December 2003 with a diagnosis of acute stroke and who had a discharge diagnosis of somatoform disorder and/or anxiety disorder according to the DSM-IV, revised criteria, and no recent stroke, according to the World Health Organisation definition.

Two investigators (CS and LC) reviewed the discharge summaries independently and collected the following data in a standardised form: (a) age; (b) sex; (c) discharge psychiatric diagnosis (somatoform disorder and conversion disorder; anxiety disorders: generalised anxiety disorder and panic disorder); (d) type (motor paresis and/or involuntary movements, sensory, visual, other) and side (right, left, bilateral) of the symptoms; (e) vascular risk factors; (f) neuroimaging data; and (g) length of stay. Disagreements were solved by consensus.

RESULTS

From 2279 consecutively admitted patients to our stroke unit, we included 35 (1.5%) discharge summaries for review. Of these, 25 patients had received a diagnosis of somatoform disorder or conversion disorder and 11 with conversion disorder, and 7 patients had a diagnosis of anxiety disorder (4 with generalised anxiety disorder and 3 with panic disorder). Three patients had other psychiatric diagnoses. Symptoms were presented on the left side of the body in 11 patients, on the right side of the body in 14, and 10 presented bilateral symptoms (table 1). There were 21 patients (60%) with vascular risk factors, of whom 11 (31.4%) had more than one risk factor. Median hospitalisation stay was 3 days.

There were no statistical differences in demographic variables, discharge psychiatric diagnosis, type of the symptoms, vascular risk factors, neuroimaging data, or length of stay between patients with left sided symptoms and those with right sided symptoms concerning (table 1). Patients with somatoform disorders had more motor symptoms most frequently than did patients with anxiety disorders (χ2 = 6.84; p = 0.02).

DISCUSSION

In this study, 1.5% of the patients admitted to a stroke unit presented symptoms unexplained by stroke or other neurological disease and fulfilling the criteria for psychiatric diagnosis. Contrary to previous studies, our results did not show a preponderance of left sided symptoms. In a meta-analysis of all studies describing patients with medically unexplained symptoms, Stone et al concluded that it is not certain that the functional symptoms are more common on the left side than on the right side of the body. They found a preponderance of the left symptoms only in the studies who investigators were aware of the laterality hypothesis before performing the study. As in that meta-analysis, we did not find a preponderance of left sided symptoms.

The younger median age at admission was in female patients with psychiatric conditions mimicking a stroke reflects the demographic characteristics of somatoform...

BOOK REVIEW

Atlas of neuromuscular diseases

This book it titled an “atlas” and subtitled “a practical guideline”. I had the expectation of a heavily illustrated book of neuromuscular conditions with annotations. The book has been designed as a comprehensive coverage of disorders of peripheral nerve (including cranial nerves), muscle, neuromuscular junction, and motor neurone. Each condition is outlined in note form, with particular emphasis on causation—which can be lengthy and repetitive. The style of the text is abbreviated and can be difficult to read. The précis can be misleading or inaccurate at times. A useful list of references is given.

It is not clear to me to whom this book would appeal. The text is probably too comprehensive and potentially misleading or confusing for students, and does not add much to those already informed. The number and quantity of the illustrations is disappointing. I had expected more clinical illustrations of the conditions described. As a practical guideline it is not helpful and in particular the therapeutic suggestions are too abbreviated, incomplete, and uncritical for clinical application. Problems to be addressed in the next edition include the use of the same nerve biopsy illustration for patients with chronic inflammatory demyelinating polyneuropathy and Charcot-Marie-Tooth disease, despite one image being rotated by 90 degrees; the illustration of text relating to genetically defined young onset spinal muscular atrophy with an elderly man who appears to have progressive muscular atrophy; and the spelling of fascioscapulohumeral (sic) dystrophy.

The authors point out that “no other book provides a complete overview in a structured and easily comprehensive pattern supported by figures and pictures”. There are, however, a number of excellent books related to diseases of muscle and nerve, some providing a wider range of clinical and pathological illustrations and a more critical review of clinical presentation, diagnosis, and treatment. At the present time the role claimed by this book remains unfilled.

R W Orrell

CORRECTION

Bone conducted stimuli should be measured in units of dB FL (force level) as a ratio to a reference force of 1 μ. These levels are 10–20 dB higher, depending upon frequency, than the values given as “SPL”. The standard parameter is 500 Hz 7ms “112 dB SPL” tone burst stimulus, obtained with a 10 V peak to peak input, corresponds to an intensity of 127 dB FL (RMS).

M S Welgampola, S M Rosengren, G M Halmagyi, et al. Vestibular activation by bone conducted sound (J Neurol Neurosurg Psychiatry 2003;74:771–8). This relates to calibration of the output of the bone conductor that was used. The audiometric calibrator was not fully aware of the specific units in which bone conductors are generally calibrated but rather was influenced by the units of the sound level meter (suitable for air conducted sound). The calibration procedure is given in the chapter on testing hearing, in which case the precise units used are not strictly relevant (and under conditions which are quite different from those that the authors used). The author has now purchased the required equipment to allow calibration of the B71, and have provided a guide to the force levels obtained:
