The clinical course of glioblastoma multiforme is characterised by invasive growth and regular recurrence. Many genetic alterations have been identified in the genesis of the disease. However, information about immunohistochemical expression in recurrent lesions is sparse.

Objectives: To determine (1) whether the p53/mdm2/EGFR/msh2 expression pattern differs in initial v recurrent glioblastoma multiforme; (2) whether a possible change in expression correlates with prognostic variables (progression-free survival time, total survival time); and (3) whether chemotherapy in addition to surgery and radiotherapy influences the p53/mdm2/EGFR/msh2 expression profile.

Methods: 27 patients were studied. They met the following criteria: histologically confirmed diagnosis of glioblastoma multiforme (WHO IV); total tumour resection at initial craniotomy; at least one recurrent glioblastoma multiforme; (2) whether a possible change in expression correlates with prognostic variables (progression-free survival time, total survival time); and (3) whether chemotherapy in addition to surgery and radiotherapy influences the p53/mdm2/EGFR/msh2 expression profile.

Results: In comparison with the initial tumour, recurrent lesions were characterised by reduced expression of p53 (p < 0.0001) and msh2 (p = 0.0012), while the numbers of mdm2 (p = 0.02), EGFR (p < 0.0001), and msh2 positive specimens (p < 0.0001) were reduced. Chemotherapy was associated with reduced msh2 expression (p < 0.0001). Immunohistochemical variables were not associated with patient survival.

Conclusions: There are significant differences in the p53/mdm2/EGFR/msh2 expression patterns in initial v recurrent glioblastoma multiforme. There may be interactions between chemotherapy and changes in the msh2 expression profile.

METHODS

Patient data

Between 1994 and 2000, 144 patients underwent craniotomy for newly diagnosed glioblastoma multiforme in our department. Forty three patients (29.9%) underwent at least one re-craniontomy for a recurrence of the tumour. The criteria for inclusion in the study were as follows:

- histological diagnosis of glioblastoma (WHO IV) without a significant oligodendrial component;
- total resection of the initial tumour, verified by the absence of a contrast enhancing region in the early postoperative computed tomography (CT) (done within 12 to 24 hours after surgery);
- patient’s age 21 years or older.

Twenty seven patients met these criteria (17 male, 10 female; median age 56 years, range 29 to 73). Seven patients underwent re-craniontomy for second tumour recurrence. All patients received postoperative irradiation of at least 54 Gy. Seventeen underwent chemotherapy (cisplatin/tamoxifen (14), gliadel (2), temozolomide for glioblastoma multiforme recurrence (1)). All tumours were located in the cerebral hemispheres.

hemispheres. In 11 cases more than one cerebral lobe was affected, while the tumour was restricted to a single lobe in 16 cases (frontal in seven, parietal in four, temporal in five).

Twenty-six patients could be followed postoperatively. In these, clinical examination and MRI studies were done every three months or when tumour recurrence was clinically suspected. Progression-free survival time was defined as the time interval between tumour resection and recrianatomy for first tumour recurrence, and could be determined in 25 patients. Total survival time was defined as the time interval between initial craniotomy and the day of the patient’s death.

**Immunohistochemistry**

Serial 4 µm slices were obtained from formalin-fixed and paraffin-embedded tissue specimens. Sections were deixed in xylene and rehydrated in alcohol followed by wet autoclave pretreatment (10 minutes at 120°C) in citrate buffer for antigen retrieval. p53, mdm2, and msh2 protein expression was detected using the following monoclonal antibodies (mAb): anti-p53 (clone DO1, Oncogene, Cambridge, Massachusetts, USA; dilution 1:800; incubation overnight at 4°C); anti-mdm2 (clone IF-2, Dianova, Hamburg, Germany; dilution 1:100; incubation overnight at 4°C); and anti-msh2 (clone AB-1, Oncogene; dilution 1:25; incubation one hour at 37°C). Staining for EGFR was done using the H11 mAb (Dako, Carpinteria, California, USA) in a dilution of 1:200 with an overnight incubation at 4°C. The Dako envision kit® was used for primary antibody detection. Staining was done using AEC-chromogen, and hemalun was used for counterstaining. p53, mdm2, EGFR, and msh2-expressing glioma specimens from earlier studies or colorectal and hepatocellular carcinomas were used as positive controls. The primary antibody was omitted for negative controls. One glioblastoma multiforme recurrence sample stained with EGFR was found to be insufficient for estimation and was excluded from the analysis.

**Staining classification and data analysis**

Different classification systems for p53, mdm2, and EGFR staining in glioblastoma multiforme have been described in published reports, whereas information about msh2 is sparse. We chose a system described by Newcomb et al and Velasco et al.16 Scoring results for p53, mdm2, and msh2 nuclear staining were classified as follows: 0, no staining; 1, detectable staining in less than 5% of the cells; 2, nuclear staining of between 5% and 60% of the cells; 3, > 60% of the cells stained. For statistical analysis, a p53 and mdm2 score of 0 and 1 was regarded as negative, while a score of 2 or 3 was regarded as positive. An msh2 score of 0–2 was regarded as reduced expression, while a score of 3 was regarded as normal expression.15,16 EGFR staining was classified as follows: -, negative; +, up to 50% of cells stained; ++, more than 50% of cells stained. For statistical analysis, + and ++ were regarded as positive.15

In order to detect possible differences in initial v recurrent tumours in the whole series, as well as with regard to the administration of chemotherapy (given v not given), the following tests were used: χ² testing to compare the numbers of positive specimens; the Wilcoxon test to compare immunohistochemical scoring in each group; and the log-rank test (Cox–Mantel) to detect possible associations between survival (progression-free survival time and total survival time) and the following variables: age (< 55 years v ≥ 55 years); sex; chemotherapy (given v not given); Karnowski performance scale score < 80 v ≥ 80; Karnowski performance scale score < 90 v ≥ 90; immunohistochemical expression positive v negative results for p53, mdm2, msh2, and EGFR in initial tumours; positive v negative results of p53, mdm2, msh2, and EGFR in first recurrences; and loss of p53, mdm2, msh2, and EGFR expression v no loss. The latter experiment was chosen because of the significant difference in the rate of immunohistochemical scores or the mean immunohistochemical score in p53, mdm2, EGFR, and msh2.

**RESULTS**

**Patient characteristics**

Twenty-three of the 26 patients died during the follow up, with a mean survival time of 532 days after diagnosis (76 weeks;
range 22 to 214 weeks). The mean progression-free survival time was 204 days (29 weeks, range 9 to 91 weeks). According to the log-rank test, we found a significant association between a Karnowski performance scale score (KPS) of at least 80% and a longer time interval to tumour progression (progression-free survival time; \( p = 0.049 \)). There was no correlation between KPS \( > 80 \) and total survival time \( (p = 0.8) \) or between KPS \( > 90 \) and survival \( (p = 0.61; \) total survival time: \( p = 0.7) \). The following clinical variables also had no significant influence on patient survival (progression-free survival time; total survival time): age \( (p = 0.1; p = 0.2) \), sex \( (p = 0.6; p = 0.9) \), and chemotherapy \( (p = 0.5; p = 0.8) \). The patient data are shown in table 1.

### Immunohistochemical expression of initial tumours and first recurrences

As shown in table 2, we found different expression profiles for mdm2, EGFR, and msh2 in initial vs recurrent glioblastoma multiforme. Additionally, the Wilcoxon test identified significant differences in immunohistochemical scores for p53 \( (p < 0.0001) \) and msh2 \( (p = 0.0012) \), again with reduced values in tumour recurrences. We observed no association between immunohistochemical expression indices and survival (progression-free survival time, total survival time). In this series, we found no significant association between p53/mdm2/EGFR/msh2 expression and age \( (\text{patients } < 56 \text{ years} \space \text{vs} \space \text{patients } \geq 56 \text{ years of age}; \text{data not shown}) \). Selected staining results for p53, EGFR, and msh2 in initial vs recurrent glioblastoma multiforme are shown in figs 1–3.

#### Immunohistochemistry and chemotherapy

We compared the p53/mdm2/EGFR/msh2 expression profiles in patients who received chemotherapy with those who did not. The use of chemotherapy was associated with reduced msh2 expression. There was no statistically significant difference in p53, mdm2, or EGFR expression. There was also no

significant difference in immunohistochemical scores as demonstrated by Wilcoxon testing. The data are given in table 3.

**Immunohistochemical expression in initial glioblastoma multiforme v first and second recurrences**

In contrast to the above results, p53/mdm2/EGFR staining profiles of the seven paired specimens with first and second recurrences seemed more random. However, three of the seven initial glioblastoma multiforme specimens showed regular msh2 expression, whereas this protein was not detected in first or second recurrences. The data are given in table 4.

**DISCUSSION**

From the results of this study, recurrent glioblastoma multiforme was characterised by the following immunohistochemical features:

- reduced amount of mdm2 and EGFR specimens (p = 0.02; p < 0.0001);
- reduced expression of msh2 (p < 0.0001);
- reduced immunohistochemical scores for p53 (p < 0.0001) and msh2 (p = 0.0012).

Three reasons for reduced immunostaining in recurrent lesions need to be considered: first, differentially expressed proteins might not be detected by the antibody used in the study; second, the expression level might actually decrease; third, recurrent glioblastoma multiforme might represent a tumour stage of generally reduced protein expression caused by further dedifferentiation.

In our study, the immunohistochemical expression of p53, mdm2, EGFR, and msh2 in initial glioblastoma multiforme was compared to that of recurrent lesions in the same patients. The study was limited in some ways: the patients were selected for re-craniotomy mainly by their performance status (this may also explain the fact that patient survival was not correlated with patient age); second, owing to the low number of patients undergoing craniotomy for glioblastoma multiforme recurrence in general, the number of specimens is small; finally, only small parts of the tumours were stained. Subclones of this tumour may have different biological behaviour and different expression patterns.

Many genetic alterations have been associated with the genesis of glioblastoma multiforme. In contrast, little has been published about immunohistochemical investigations in recurrent glioblastoma. Strik et al described upregulation of antiapoptotic proteins and a downregulation of the proapoptotic bcl-2 family member bax in recurrent v initial glioblastoma multiforme. These differences were highly significant in patients treated with chemotherapy and radiotherapy but showed only a trend in untreated patients. Some investigators have reported an inverse correlation of Ki67 PI with progression-free survival time and total survival time in

GBM, glioblastoma multiforme.
gliomas of all WHO grades.\textsuperscript{20–21} Deininger \textit{et al} described a correlation between a high p53 score (detected by the mAb DO-1 which detects wild type as well as mutated p53) and a short time to tumour progression only in those patients who underwent radiochemotherapy.\textsuperscript{22} They furthermore found that radiation treatment led to a reduction in p53 scores (detected by the mAb DO-7 which detects mainly mutated p53 protein) and an increase in bcl-2 scores.

A decrease in DO-1 detected p53 expression, as demonstrated by Wilcoxon testing, could indicate a decrease in wild-type p53 in recurrent tumours. In comparison with the study by Deininger \textit{et al}, all of our patients received radiotherapy and most of them underwent additional chemotherapy. However, we found no significant association between DO-1 detected p53 expression and progression-free survival time. With regard to the fact that p53 induces mdm2 transcription, mdm2 protein levels could be reduced because of decreased p53 protein expression. On the other hand, many splicing variants have been described for mdm2 protein.\textsuperscript{23} These could be differentially expressed in different stages of the disease. However, there was no significant association between p53/mdm2 expression and survival. EGFR has been described as an important factor in glioblastoma growth.\textsuperscript{2} We observed reduced expression in recurrent tumours but no significant association between EGFR detection or EGFR loss and survival.

In agreement with the results of Friedman \textit{et al},\textsuperscript{11} msh2 was expressed in the majority of glioblastoma multiforme specimens. Those investigators furthermore reported no significant association between msh2 expression and the response of glioblastoma and anaplastic astrocytoma to temozolomide chemotherapy. We found that the administration of chemotherapy (mainly cisplatin/tamoxifen) was associated with reduced expression of msh2 in recurrent lesions (p < 0.0001). It should be noted that temozolomide chemotherapy (n = 1) was given after re-craniotomy for tumour recurrence and thus could not have had any influence on the immunohistochemical expression profile.

Conclusions

Bearing in mind the limitations listed above, recurrent glioblastoma multiforme is characterised by significantly reduced p53/mdm2/EGFR/msh2 expression. The administration of chemotherapy was associated with reduced expression of the MMR protein msh2. Our results indicate that significant changes occur during the life span of patients suffering from glioblastoma. However, neither p53/mdm2/EGFR/msh2 expression nor reduced expression in recurrent glioblastoma multiforme was associated with survival.
