CSF galanin and cognition after shunt surgery in normal pressure hydrocephalus

J Neurol Neurosurg Psychiatry 2003;74:1272–1277

Background: “Normal” pressure hydrocephalus (NPH) is associated with injury to neurotransmitter and neuropeptide systems that recovers after surgery. This could be linked to changes in galanin, a neuropeptide with inhibitory effects on basal forebrain cognitive function.

Objective: To examine changes in CSF galanin concentrations in patients with normal pressure hydrocephalus undergoing shunt surgery, and to investigate the relation between these changes and cognitive functioning.

Methods: Eight patients underwent surgery for idiopathic normal pressure hydrocephalus. Lumbar CSF galanin determinations, cognitive status, and clinical status were quantified before operation and six months after. Cognition was assessed by an extensive battery of tests measuring attention, memory, speed of mental processing, visuospatial function, and frontal lobe function.

Results: CSF galanin concentration decreased after surgery. This reduction correlated with improved clinical and cognitive functioning, specifically with attention and visuomotor speed, visuoconstructive and frontal functioning, and clinical status according to the NPH scale, including the sphincter and cognitive components.

Conclusions: The cognitive and clinical improvement after shunt implantation correlated with CSF galanin levels, suggesting that the distribution or function of this agent involves cerebral structures that may be associated with the fronto-subcortical deficits underlying cognitive dysfunction in normal pressure hydrocephalus.

This study is a continuation of previous work investigating alterations in cerebrospinal fluid (CSF) neuropeptides involved in the modulation of cognitive processes in patients affected by dementia. In our earlier studies we determined CSF concentrations of cognition related neuropeptides in patients with Alzheimer’s type dementia, multi-infarct dementia, and dementia related to normal pressure hydrocephalus compared with normal subjects. Our overall findings, together with the experience of other investigators in this field, suggest that dementias of diverse aetiology show similar CSF neuropeptide alterations, and that it is unlikely that specific neuropeptide markers will be found that can differentiate among the various dementias. Nevertheless, these determinations are useful for studying the brain dysfunction and damage that occur in several dementia types.

Cognitive impairment together with gait disturbances and urinary incontinence are common and important consequences of normal pressure hydrocephalus. At present, the only effective treatment for the progressive form of this disease is CSF shunt placement, which improves clinical symptoms in a substantial proportion of patients. By evaluating changes in CSF neuropeptide levels after shunting and correlating these with improvements in cognitive performance, it is possible to investigate the implications of specific neuropeptides for the cognitive symptoms of normal pressure hydrocephalus. The results obtained in the few studies undertaken along these lines showed significant increases in CSF neuropeptide levels after shunt surgery that correlated with clinical improvement; however, no correlations were found between cognitive improvement and the neuropeptide changes observed.

As we indicated in a previous study, the most plausible explanation for the persistence of neuropsychological impairment in the presence of improved neuropeptide levels is that irreversible neuronal functional injury occurs with the development of hydrocephalus. This probably takes place at the level of certain cortical synapses, as has been demonstrated in experimental studies.

Galanin, a 29 amino acid peptide originally isolated from porcine intestine, is widely distributed in the mammalian central nervous system, where it is involved in many central functions, including those related to cognition. Several lines of evidence suggest that the important role of this peptide in attention and memory is based on its modulation of cholinergic basal forebrain activity. In rats, galanin inhibits hippocampal acetylcholine neurotransmission and impairs the performance of several attentional and memory tasks. In addition, galanin is overexpressed in the basal forebrain and cortex of patients with Alzheimer’s disease. The cognition mediated function of galanin in forebrain pathways has led us to examine changes in CSF galanin levels in patients with normal pressure hydrocephalus undergoing shunt surgery and to investigate the relation between these changes and cognitive functioning, as determined by an extensive battery of neuropsychological tests. On the basis of the cognitive inhibitory actions of galanin, we hypothesised that galanin concentrations would decrease after shunt surgery and that the changes would be associated with neuropsychological improvement.

METHODS

Patients

Eight patients (three men and five women) with idiopathic normal pressure hydrocephalus were included in the study.

Abbreviations: AVLT, auditory-verbal learning test; NPH, normal pressure hydrocephalus; RDRS, rapid disability rating scale; TMT, trail making test; WAIS, Wechsler adult intelligence scale; WMS-III, Wechsler memory scale-III
Cerebrospinal fluid samples and galanin assay

Lumbar CSF samples (10 ml) were taken before and six months after shunting. CSF was obtained between 8:00 and 10:00 am, after at least eight hours of fasting and bed rest. CSF was collected in plastic tubes containing trasylol (1000 kIU/ml) to prevent proteolysis, immediately frozen at −80°C.

Immunoreactive galanin was measured by a competitive radioimmunoassay (RIA; Peninsula Laboratories, San Carlos, California, USA) after an extraction-concentration procedure. The peptide was extracted from CSF samples (3 ml) by absorption into columns packed with octadecasilyl silica (C18sep-pak., Water Associates, Milford, Massachusetts, USA) after an extraction-concentration procedure. The remaining six patients.

Their mean (SD) age was 73.4 (6.8) years, range 60 to 81. All patients had ventricular dilatation (Evans’ index > 0.30) and a history of gait disturbance, cognitive deficits, or sphincter dysfunction. The diagnosis of normal pressure hydrocephalus and the decision to implant a shunt were based on our protocol of the study and management of this syndrome, and included clinical features, neuroimaging, continuous intracranial pressure monitoring, and CSF dynamics.

Neuropsychological assessment

Eleven psychometric tests measuring attention, verbal and visual memory, speed of mental processing, visuospatial functioning, and frontal lobe functions, and four clinical and functional scales were administered to all patients before and six months after shunting by the same examiner, who was blind to the biochemical results. These included the following:

- **Attention and memory**: information and orientation subtest, mental control subtest, and visual reproduction I and II subtests of the Wechsler memory scale–R (WMS–R); memory span for digits subtest of the Wechsler adult intelligence scale (WAIS); and two alternate versions of the auditory-verbal learning test (AVLT);

- **Frontal functions**: trail making tests (TMT) A and B; word fluency (“FAS” and animals) conducted over one minute each; and Stroop test (a computerised version of the test in which mean time for correct responses in the interference condition are recorded);

- **Perceptual functions**: judgment of line orientation test and block design subtest of the WAIS;

- **Psychomotor speed**: Purdue pegboard test and simple reaction time (simple colour dots matching trial from the Stroop test);

- **Clinical status and daily life activities**:

  - 1. The NPH scale (normal pressure hydrocephalus scale), which evaluates the three main parts of the normal pressure hydrocephalus syndrome: gait, cognitive function, and sphincter disturbances and ranges from a score of 3 (patient is not ambulatory, has severe dementia, and urinary and faecal incontinence) to 15 (normal gait, cognitive disturbances only found by specific tests, and no sphincter dysfunction).

  - 2. The rapid disability rating scale (RDRS-2), which assesses the degree of disability and is composed of 18 items scored on a scale of 1 to 4; a global score of 18 indicates that the patient is totally independent and a score of 72, totally dependent.

  - 3. The modified Stein and Langfit scale, including five grades, starting from grade 0 in which there is no neurological deficit and the patient is able to work or perform the same duties as before the disease, to grade V in which the patient is bedridden or vegetative without any spontaneous activity or verbal contact;

  - 4. The informant’s test, which registers functional behaviour changes as reported by a close relative. It consists of 17 items scored on a five point basis (1, much better; 2, a bit better; 3, no change; 4, a bit worse; 5, much worse).

Statistical analysis

Non-parametric tests were used for statistical analyses. These included the Wilcoxon matched pairs signed ranks test to

analyse preoperative and postoperative differences, and Spearman’s rank correlation test to study the relation between neuropeptide concentrations and neuropsychological and behavioural functioning. In addition, we calculated the percentage of change between basal and postoperative conditions: [(postoperative − preoperative)/preoperative] × 100. Significance was set at a probability (p) value of 0.05. Values are given as mean (SD) or median (interquartile range).

RESULTS

Preoperative status

Before treatment, all patients had abnormal gait according to the NPH scale: three had abnormal but stable gait, one was able to walk independently but was unstable or subject to falls, three were unable to walk without help, and one was unable to walk at all. Cognition (NPH scale) was also impaired in all cases: three had memory problems, three had significant memory problems and behaviour disturbances of varying severity, and two had severe dementia. Sphincter control was as follows: one had no sphincter disturbances, one had urinary urgency, four had sporadic urinary incontinence, one had continuous urinary incontinence, and one had urinary and faecal incontinence. Five patients were dependent on others for activities of daily living (Stein and Langfit’s scale grade IV), and three required some help or supervision (grades II and III), and two were able to carry out daily activities independently (grade I).

As can be seen in table 2, statistical comparisons between preoperative and postoperative neuropsychological performance showed significant improvement in verbal memory (AVLT learning), visuoconstructive functioning (block design), and psychomotor speed (TMT-A and pegboard right hand), and in a daily life activities scale (informant’s test).

Neuropeptide changes

Mean CSF galanin concentration showed a statistically significant decrease from 12.3 (2.8) pg/ml on preoperative analysis to 8.8 (4.9) pg/ml at the six month assessment (z = −2.10; p = 0.036).

Relation between percentage change in galanin levels and neuropsychological changes following surgery

Decreases in CSF galanin were significantly related to improvement in several clinical and neuropsychological tests. The per cent changes in galanin concentrations correlated with changes in the NPH scale (overall: r = −0.76, p = 0.028; cognitive component: r = −0.86, p = 0.006; and sphincter subcomponent: r = −0.80, p = 0.017); attention and frontal lobe functioning (digit span forward: r = −0.82, p = 0.025; trail making test A: r = 0.86, p = 0.014; Stroop test: r = 0.94, p = 0.005); visuospatial functioning (block design: r = −0.86, p = 0.007), and visuomotor speed (pegboard right: r = −0.83,
No relation was found between age, education, and duration and severity of normal pressure hydrocephalus, and post-shunt cognitive and neuropeptide changes.

**DISCUSSION**

The patients with idiopathic normal pressure hydrocephalus in our study had a significant postoperative reduction in CSF galanin concentrations. This finding agrees with previous research indicating the reversibility of some functionally injured neurotransmitter and neuropeptide systems following shunt surgery.

Our results showed a correlation between improved functional and cognitive impairment after shunt implantation and CSF galanin changes. Postoperative decreases in galanin concentrations were related to improvements in attention and visuomotor speed, visuoconstructive and frontal functioning, and clinical status according to the NPH scale, including the cognitive and sphincter components. These good correlation results for galanin—in contrast to the poor correlations described for somatostatin, neuropeptide Y (NPY), corticotropin releasing factor (CRF), and vasoactive intestinal peptide (VIP) in similar studies—can be attributed to the different localisation of these peptides in the neocortex and the basal forebrain, together with the distinct type of neuronal injury resulting from abnormal intracranial pressure in these specific brain regions. Early studies investigating peptide regional brain distribution show that the cortex contains high concentrations of somatostatin, NPY, CRF, and VIP, and that the hippocampal formation is also very rich in these peptides.

Similar work investigating the localisation of galanin immuno-reactive neuronal structures in rat CNS showed a wide distribution of the peptide, including some areas of the cortex; however, the major galanin positive fibres were seen in the septal-basal forebrain, hypothalamus, pons/medulla, and spinal cord. Focusing on the basal forebrain system, galanin is co-localised with choline acetyltransferase in a subpopulation of neurones in the septal nucleus and diagonal band of the Broca area which project to the hippocampus (septohippocampal projection, through the fimbria-fornix), whereas the cholinergic neurones in the nucleus basalis of Meynert, innervating the cerebral cortex, do not contain detectable levels of the peptide. The intraventricular location of the fimbria-fornix and septum may make this pathway anatomically vulnerable at an early stage of hydrocephalus. However, these structures may have some potential to recover, as described experimentally.

Recent studies in rats suggest a predominant inhibitory action of galanin on attention and working memory, which is consistent with the role of the septohippocampal cholinergic system in processes involved in attention. In our study of patients with idiopathic normal pressure hydrocephalus, galanin was not only related to attention but also to speed, inhibition, and verbal fluency. All these functions, however, are part of the fronto-subcortical systems in which galanin may also play a role.

Thus in our study galanin was strongly related to several cognitive functions that may be associated with the frontal
lobe deficits underlying cognitive dysfunction in normal pressure hydrocephalus. The neuropsychological profile in the dementia that accompanies normal pressure hydrocephalus has been documented in a small number of studies. Adams et al described the clinical picture of their patients as a disabling dementia with psychomotor retardation. The cardinal features, consistent with frontal symptoms, were slowness and paucity of thought and action and mild memory impairment. The condition was also characterised by a lack of spontaneity and initiative, faulty concentration, distractibility, lack of interest, apathy, and inertia. Other studies have confirmed this predominant involvement of frontal-subcortical functions. Also consistent with this neuropsychological pattern is the significant improvement in long term verbal memory, visuospatial functioning (block design subtest), and speed (TMT-A and pegboard right hand) in our patient sample following surgery. These tests are highly sensitive measures, capable of detecting small changes. In the remaining tests measuring the same functions, there was also an improvement following surgery although the differences did not reach statistical significance. The lack of statistically significant changes in all tests within the same domain could also reflect the fact that they assess different aspects of the domain.

Conclusions
In this report we have shown that the improvement in functional and intellectual impairment after shunt implanta
tion is correlated with CSF galanin levels, which indicates that the distribution or function of this peptide involves cerebral structures that have some potential for recovery. The results of this preliminary work suggest that galanin is related to several cognitive functions, particularly fronto-subcortical function. It would be of particular interest to include this peptide in the development of new pharmacological strategies in the light of favourable results already obtained with the use of galanin antagonists in certain types of neurological impairment.

HISTORICAL NOTE

Charcot on “provoked trepidation”, or clonus

The classic signs of upper motor neurone lesions became recognised in the second half of the 19th century. Charcot and his colleagues first distinguished them from the flaccid weakness of poliomyelitis, posterior column lesions (locomo- motor ataxy), neuropathic, and myopathic lesions. The contributions of Erb,1 Marshall Hall,2 and Westphal3 to the related tendon reflexes are well known, but the origins of clonus are less clearly portrayed. The importance of these signs can hardly be overestimated. In Charcot’s lectures (references as in his text) he said of clonus:

“. . .known in France under the name of provoked trepidation, or provoked spinal epilepsy. German writers call it the foot-phenomenon (Fussphoenomen) or ankle clonus. But the discovery of this sign belongs to French clinical observers. Since 1863, . . . it has been practised daily in the wards of La Salpêtrière by M. Vulpian, by myself, and by our pupils.”

“. . .it is habitually absent in the motor inabilité connected with locomotor ataxie, infantile spinal paralysis, and in other conditions of the same kind, whereas it is never wanting in paralysis of cerebral or spinal origin, in which contracture exists or tends to become established.”

“The phenomenon may be described as follows. The paralysed lower limb of a hemiplegic patient is supported by placing one hand beneath the ham so that the patient’s leg may hang loose and swing; if now, with the other hand, the point of the foot is suddenly raised, a series of shakes is at once provoked, which collectively constitute a kind of rhythmical movement or oscillatory trembling more or less regular and persistent. Spinal trepidation presents the more interest from the fact that, as a rule, no trace of it exists in the normal state. Thus Herr Berger, who has made some observations on the matter, only discovered it three times in 14 000 apparently healthy subjects (mostly soldiers):”

“I must, however, repeat emphatically that, in the domain of pathology, this is not a constant phenomenon, since in certain spinal affections it is absent, whilst in others the rule is for it to be present. Briefly, it is one of the characteristic features of the group of spasmatic [Charcot often uses the term spasmotic for spastic] paralyses; and to this category belongs central hemiplegia with secondary degeneration of the pyramidal tract.”

“When late contracture has taken place, this phenomenon is nearly constant, but it frequently precedes the contracture by several weeks. In a patient, now an inmate in the infirmary of La Salpêtrière, it began to manifest its presence a week after the attack, and a fortnight later rigidity of the lower limb first made its appearance.”

“In another patient, it did not appear until a month after the attack, and the muscular rigidity began to be evident in the course of the second month.”

“M. Dejerine has recently pointed out that this symptom is occasionally present in both lower limbs, and we shall see that this is sometimes the case with contracture.”

“In hemiplegic patients possessing some slight power of movement, this same trepidation which, in certain cases extends to the entire limb, may also manifest itself in consequence of a voluntary movement. The phenomenon in question is reflex, as I purpose to demonstrate at greater length on a subsequent occasion. . .”

“An analogous phenomenon is occasionally produced when the hand of a hemiplegic patient is suddenly lifted up by the tips of the fingers. Moreover, these patients, on raising the paralysed arm, often experience a trembling similar to that which occurs in the lower limb under like circumstances. But the wrist-phenomenon, provoked or spontaneous, is much more uncommon than the corresponding effect which we call the foot-phenomenon.”

“These two signs, as we shall show, belong to the same category as those recently introduced into the semeiotics of spinal affections by Westphal, and afterwards by Erb, under the collective term of tendon-reflexes.”
