PAPER

Do stroke patients with normal carotid arteries require TEE for exclusion of relevant aortic plaques?

A Harloff, M Handke, A Geibel, E Oehm, B Guschlauer, M Olschewski, A Hetzel

Objectives: This study investigated (a) the hypothesis that stroke patients with aortic atheroma would show comparable atherosclerotic changes in the carotid arteries, which are easily accessible for ultrasound evaluation and (b) the possibility of carotid duplex sonography as a replacement for transoesophageal echocardiography (TEE) for the exclusion or prediction of relevant aortic plaques.

Methods: In 301 consecutive patients (mean age 62 years) with acute cerebral ischaemia, two dimensional ultrasound measurements were taken of common carotid artery intima media thickness (IMT) and maximal plaque area (PA) and the local degree of internal carotid artery (ICA) stenosis were determined. Maximal aortic wall thickness (AWT) was assessed by TEE.

Results: An IMT $<$ 0.9 mm yielded a negative predictive value (NPV) of 95.8% for exclusion of aortic atheromas $\geq$ 4 mm and an NPV of 100% for the exclusion of aortic thrombi. However, positive predictive value of IMT $>$ 0.9 mm was low (29.6%), increasing only slightly in the presence of carotid plaques (33%). Incidence of aortic thrombi was significantly higher with $\geq$ 50% compared with $<$ 50% ICA stenosis (11.3% v 3.9%, respectively). IMT and PA correlated moderately with AWT ($r = 0.47$, $r = 0.53$, respectively; $p < 0.001$). Systolic blood pressure, coronary heart disease and peripheral artery disease, increased IMT, and ICA stenosis $\geq$50% were independently related to AWT $\geq$ 4 mm.

Conclusions: A high NPV of normal carotid ultrasound does not support routine TEE for the exclusion of complex aortic plaques as a high risk source of cerebral embolism. However, in patients with carotid atherosclerosis, particularly in those with ICA stenosis $\geq$50%, TEE should be performed to exclude an additional high risk source for stroke.

Increased carotid intima media thickness (IMT) indicates generalised atherosclerosis and is a strong predictor of ischaemic stroke. Similarly, aortic atherosclerosis is related to vascular risk factors and is also independently associated with cerebral ischaemia. The prevalence of both carotid artery disease and thick thoracic aortic plaques is comparable to that of atrial fibrillation in patients with ischaemic stroke. An association between carotid and aortic atherosclerosis has been shown in smaller series and in a large epidemiological study. However, there has been no prospective evaluation of the exact relation using carotid duplex sonography and transoesophageal echocardiography (TEE) in a larger and unselected cohort of patients with ischaemic stroke.

We hypothesised that patients with aortic plaques would also show atherosclerotic changes in carotid arteries. These atherosclerotic changes are easier to evaluate with ultrasound and could therefore serve as an indicator for aortic plaques. Thus the aims of our study were:

- to determine the precise association of carotid and aortic atherosclerosis in a larger stroke population, taking into consideration both cardiovascular risk factors and laboratory markers of atherosclerosis
- to test the reliability of carotid duplex sonography as a replacement for TEE in the exclusion or prediction of clinically relevant aortic plaques.

PATIENTS AND METHODS

Study population

We prospectively enrolled a total of 384 consecutive patients admitted to our stroke unit with acute cerebral ischaemia within the last 16 months. The local ethics committee approved the study and all patients gave written informed consent. TEE was not done in 56 patients for the following reasons: patient refused examination ($n = 27$), clinical contraindication ($n = 19$), and non-compliance or gastrointestinal tract obstruction ($n = 10$). We excluded 12 patients because of unclear delineation of the IMT complex and 15 patients because the diagnosis on discharge was not transient ischaemic attack or ischaemic stroke. Hence the final sample consisted of a consecutive series of 301 patients.

The study protocol included a prospective evaluation of cardiovascular risk factors. All patients underwent cranial computed tomography or magnetic resonance imaging of the brain or both, duplex sonography of extracranial and intracranial arteries, transthoracic echocardiography, and TEE. Blood pressure was measured every 60 minutes on the stroke unit and average systolic and diastolic values were obtained from patients’ charts as separate variables within the time interval of 24–48 hours after the qualifying event.

Blood samples were taken from the antecubital vein after overnight fasting. Cholesterol and triglycerides were measured using enzymatic methods and reagents (WAKO Chemicals; Neuss, Germany). Lipoproteins were measured with rapid electrophoresis (Helena Laboratories, Gateshead, UK). Glycosylated haemoglobin (HbA1c) was measured with high performance liquid chromatography (glycohaemoglobin analyser; Tosoh Corp, Tokyo, Japan).

Abbreviations: AWT, aortic wall thickness; CCA, common carotid artery; DA, dimensions of atherosclerosis; HbA1c, glycosylated haemoglobin; ICA, internal carotid artery; IMT, intima media thickness; NPV, negative predictive value; PA, plaque area; PPV, positive predictive value; TEE, transoesophageal echocardiography
Evaluation of risk factor variables
We considered patients to be exposed to a cardiovascular risk factor when one of the following criteria was satisfied:

- age >60 years
- male sex or ≥5 years after menopause for women
- hypertension—that is, history of hypertension or blood pressure exceeding 160 mm Hg systolic or 95 mm Hg diastolic on two occasions in the hospital
- diabetes mellitus—that is, history of diabetes or fasting glucose exceeding 126 mg/dl or patient requiring glucose lowering therapy
- hypercholesterolaemia—that is, total plasma cholesterol of >200 mg/l in the previous 12 months or documented hypercholesterolaemia requiring lipid lowering drug therapy
- smoking habit—that is, consuming ≥1 cigarette daily
- documented previous ischaemic stroke/transient ischaemic attack
- coronary artery disease—that is, documented coronary artery stenosis, percutaneous transluminal coronary angioplasty or coronary artery bypass, myocardial infarction
- peripheral artery disease—that is, documented peripheral artery disease, percutaneous transluminal angioplasty, vascular surgery.

Assessment of carotid atherosclerosis
Two trained sonographers assessed the carotid arteries using duplex ultrasound scanning with a 4–7 MHz linear array scanner (ATL, HDI 3500; ATL Bothell, USA). With the patient in the supine position, a careful search was performed of all interfaces of up to 12 different sites in the transverse and sagittal planes (right and left, near and far walls, proximal and distal common carotid artery (CCA), and internal carotid artery (ICA)). When an optimal longitudinal image of the CCA was obtained, it was frozen and magnified at the time of the R wave on the electrocardiogram (ECG) and stored on S-VHS videotape. Quantitative measurements of IMT were done offline. The readers who evaluated the ultrasound images on videotape were blinded to patient demographics and the results of the TEE examinations. IMT was measured twice on the far wall at a distance of 4 cm and 1 cm proximal to the bifurcation on both sides of the CCA on a plaque free site. For each patient the common carotid IMT was taken as the mean of eight IMT measurements (IMTmean). Based on the IMTmean, patients were classified into the following categories: I, ≤0.9 mm; II, >0.9 mm–1.05 mm; II, >1.05 mm–1.2 mm.

Carotid plaque was defined as a focal circumscribed increase in intimal wall thickness. We measured plaque area (PA) in the most stenotic plaque of the bifurcation/ICA by multiplying plaque length by thickness. We estimated the dimensions of atherosclerotic change (DA) in the carotid arteries in a manner similar to that used previously by others19. IMTmean×80 mm (80 mm represents the 40 mm long segments of the left and right CCA proximal to the bifurcation)+PA of both ICA. In accordance with the European Carotid Surgery Trial (ECST) protocol19 the degree of ICA stenosis was defined as the “local” degree of stenosis and categorised as either <50% (on both ICAs) or ≥50% (left or right ICA). Corresponding values for “distal” degree of ICA stenosis are approximately <30% and ≥30%, respectively.20

Assessment of aortic atherosclerosis
TEE was performed with a 5 MHz multiplane probe (ATL, HDI 3500) and recorded on S-VHS videotape. An experienced senior echocardiographer, blinded to patient demographics and carotid artery scanning data, reviewed the findings offline. The ascending aorta and the aortic arch including the outlet of the left subclavian artery were imaged in short axis and long axis views. Findings distal to the left subclavian artery (that is, in the descending aorta) were not considered in this study. Atherosclerosis was defined as irregular and circumscribed intimal thickening with increased echogenicity.20 Maximal aortic wall thickness (AWT) was measured and the presence of mobile thrombi documented. We classified the patients similar to a previous study: I, AWT <0.8 mm; II, plaques 1.0–3.9 mm thick; III, plaques ≥4.0 mm thick.

Statistical analysis
We used the SAS statistical package (version 6.12) for all statistical analyses. Data are presented as mean and standard deviation for continuous variables and as absolute and relative frequencies for categorical variables. We used Fisher’s exact test to detect statistically significant relations between categorical variables, and for continuous variables, t tests or Wilcoxon’s tests were used as appropriate; all tests used were two sided. Correlations between selected variables were estimated by calculating Pearson’s correlation coefficient. Carotid artery ultrasonographic data and corresponding TEE data were compiled into a 2×2 contingency table to allow calculation of predictive values. Multivariate analyses (analysis of covariance) were performed for continuous dependent variables (IMT and AWT) and multiple logistic regressions for dichotomised dependent variables (AWT <4 mm v AWT ≥4 mm). We set the level of significance at 5%. We report nominal p values not adjusted for multiple comparisons.

RESULTS
Baseline characteristics and cardiovascular risk factors
The baseline characteristics of the 301 study participants are shown in table 1. Complete data on blood lipids and HbA1c were available for 272 patients (90.4%). Ultrasound measurements are given in table 2. Both IMT and AWT increased significantly with the number of cardiovascular risk factors (p<0.05).

Carotid artery duplex ultrasonography data
In the univariate regression analysis IMT correlated with increased systolic blood pressure and HbA1c (p = 0.001), LDL/HDL cholesterol ratio (p = 0.025) and decreased high density lipoprotein (HDL) cholesterol level (p<0.01), with age >60

LDL, low density lipoprotein; HDL, high density lipoprotein.
years, hypertension and diabetes (p<0.001), male sex, and coronary and peripheral artery disease (p<0.05). Correlations of multivariate regression analysis are given in table 3.

**Aortic findings**

Univariate regression analysis demonstrated correlation between AWT and increased systolic and diastolic blood pressure (p = 0.001), HbA1c (p<0.01), HDL cholesterol (inversely) (p<0.05) and with age >60 years, hypertension, diabetes, smoking, previous brain ischaemia, coronary and peripheral artery disease (p<0.001). Correlations of multivariate regression analysis are shown in table 3.

**Correlation between carotid and aortic atherosclerosis**

The correlation between IMT and AWT was moderate (fig 1) and highest between the total dimension of carotid atherosclerosis and AWT (fig 2). The correlation of IMT and AWT with carotid plaque area was similar (r = 0.51 and r = 0.53, p<0.001).

**Carotid stenosis and aortic findings**

IMT and AWT were higher in patients with ICA stenosis ≥50% (table 2). Aortic plaques ≥4 mm occurred in 21.6% (65/301) of the entire study population and they were almost three times more frequent with ≥50% stenosis (43.7% v 14.8%). Mobile aortic thrombi were detected in 5.6% of patients (17/301); the AWT was ≥4 mm in 15 (88.4%) and <4 mm in only two of these patients. Similarly, in patients with ≥50% stenosis the incidence of aortic thrombi was almost three times higher in patients with <50% stenosis (11.3% v 3.9%). There was no statistically significant difference between IMT and AWT, and the incidence of AWT ≥4 mm or aortic thrombi, in 50–79% compared with ≥80% ICA stenosis.

**Predictive values**

IMT ≤0.9 mm, seen in 95 of our patients (31.6%; table 2), almost excluded AWT ≥4.0 mm (negative predictive value (NPV) 95.8% (4/95)). In the four false negatives, the AWT ranged from 4.1 mm to 4.5 mm. The combination of IMT ≤0.9 mm and absence of carotid plaques, seen in 49 patients (16.3%), increased the NPV to 100%. On TEE none of the 95 patients with IMT ≤0.9 mm had aortic thrombi, but 2/95 (2.1%) had left atrial thrombi. The positive predictive value (PPV) of IMT >0.9 mm for the presence of aortic plaques ≥4 mm was low (29.6%; 61/206), even when carotid plaques were taken into account (33.0%, 59/179).

**DISCUSSION**

We present the first prospective investigation of a large cohort of consecutive patients with recent brain ischaemia...
evaluated by carotid ultrasound and TEE. We found a high NPV of normal carotid arteries for aortic thrombi and plaques \( \geq 4 \) mm and a moderate correlation of atherosclerosis in the carotid arteries and in the aorta.

With regard to correlation between IMT, plaque area, and DA with AWT, our results are comparable with other studies. Patients with ICA stenosis \( \geq 50 \)\% had increased IMT and AWT, in particular, a three times higher incidence of superimposed aortic thrombi compared with those with lower grade ICA stenosis. However, the overall incidence of aortic thrombi was lower than has been described before, and the thrombi were found with all degrees of ICA stenosis, not just with \( \geq 80 \)\%. Therefore, TEE screening of the aorta seems to be of benefit in patients with advanced carotid atherosclerosis (that is, especially in ICA stenosis \( \geq 50 \)\%) particularly if localisation of brain infarction is at odds with the site of the stenosis. The detection of aortic thrombi on TEE may then change the secondary prevention strategy. However, the optimal therapy for aortic thrombi or plaques \( \geq 4 \) mm has not yet been established: in three smaller studies, warfarin was superior to aspirin in complex aortic plaques whereas in a larger retrospective analysis only smaller studies warfarin was superior to aspirin in complex plaques.

In the ongoing Aortic arch Related Cerebral Hazard trial of carotid and aortic atherosclerosis, representing the same pathophysiological mechanism, providing reliable predictive values. This discrepancy between the results is most likely due to different study populations, examination of different segments of the aorta and the evaluation of aortic atheroma by x-ray versus ultrasound.

In agreement with others, we found that the PPV of carotid ultrasound for relevant aortic atheromas is low. Shimizu et al. showed a moderate association between carotid and aortic atherosclerosis and a significant increase in complex aortic plaque probability with increasing carotid IMT. Our results are comparable, especially for patients with \( \geq 50 \)\% ICA stenosis. However, in Shimizu’s study a cohort consisting of only 147 preselected patients was examined and their results thus might not be representative for all stroke causes. Unfortunately, exact PPVs or NPVs of carotid IMT for relevant aortic plaques have not been provided. Fasseas et al. reported similar predictive values for complex aortic plaques in 64 stroke patients with severe carotid atherosclerosis (that is, IMT \( \geq 2.0 \) mm) whereas our results imply that even considerably less advanced carotid atherosclerosis helps in identifying patients with relevant aortic atherosclerosis. In 62 patients undergoing TEE for cardiological indications, the PPV of carotid plaques (that is, IMT \( \geq 1.3 \) mm) for aortic atherosclerosis (that is, luminal irregularity or wall thickness \( >3 \) mm, plaques with mobile thrombi or ulcerations) was 83\%, whereas NPV was only 63\%. These findings are in contrast with the studies cited above and with our results but this is probably because of the different definitions used by Kallikazaros et al. for carotid and aortic plaques. After the trials on aortic atherosclerosis, it seems to be clinically more relevant to exclude plaques \( \geq 4 \) mm thickness.

As shown previously, in our patients correlated with classic cardiovascular risk factors. The independent prediction of aortic plaques \( \geq 4 \) mm by indicators of peripheral atherosclerosis such as ICA stenosis, coronary, and peripheral artery disease emphasises the systemic nature of atherosclerosis.

**Limitations of the study**

Owing to the different ultrasound probe frequencies, measurement techniques, and patient populations, only limited comparisons can be made between studies on IMT. Measurement of mean IMT on the far wall of the CCA is a frequent technique, providing the clearest target for measurement and allowing use of an automatic detection system. The use of this technique and an ultrasound probe with higher resolution for both carotid and aortic ultrasound in the present study might have increased the accuracy of IMT and AWT measurements to a certain extent. However, at the time of the study it was not possible to do this in our stroke unit. Moreover, three dimensional ultrasound might have provided additional information in terms of plaque size and morphology in both territories.

**Summary**

A normal carotid ultrasound offers a high NPV for the exclusion of relevant aortic atherosclerosis and makes TEE indispensable for this indication in stroke patients. Patients with \( \geq 50 \)\% ICA stenosis have a high risk of severe aortic or aortic thrombi. For a sophisticated planning of secondary prevention they should undergo TEE examination of the aorta.
