### SHORT REPORT

**Prognosis of conservatively treated patients with Pott’s paraplegia: logistic regression analysis**

J Kalita, U K Misra, S K Mandal, M Srivastava

**Objective:** To evaluate the prognostic significance of various clinical, radiological, and neurophysiological findings in conservatively treated patients with Pott’s paraplegia, using multiple regression analysis.

**Methods:** The study included 43 patients with Pott’s paraplegia, managed conservatively. The diagnosis of Pott’s spine was based on clinical, magnetic resonance imaging, and computed tomography or ultrasound guided aspiration biopsy. All patients were examined clinically, and motor evoked potentials (MEPs) to lower limbs and tibial somatosensory evoked potentials (SEP) were recorded. Outcome at six months was defined as good or poor. For evaluating predictors of outcome, 15 clinical, investigative, and evoked potential variables were analysed, using multiple logistic regression analysis.

**Results:** The age range of the patients was 16–70 years, and 22 were female. Mild spasticity with hyperreflexia only was seen in 13 patients. In the remaining, weakness was severe in eight, and moderate and mild in 11 patients each. Twenty patients had loss of joint position sensation. MEP and SEP were abnormal in 19 and 18 patients, respectively. On multiple regression analysis, the best model predicting six month outcome included power, paraplegia score, SEP, and MEP.

**Conclusion:** Patients with Pott’s paraplegia are likely to recover completely by six months if they have mild weakness, lower paraplegia score and normal SEPs and MEPs.

---

**S**pinal tuberculosis is the commonest form of bone and joint tuberculosis in developing countries and constitutes 1% of all tuberculosis. There has been a resurgence of tuberculosis in the developed world because of acquired immune deficiency syndrome, organ transplantation, immunosuppression, and immigration. It has thus become a more important problem now than it was in the recent past.

Modern pharmacotherapy and imaging have changed the outlook of neurotuberculosis. With computed tomography (CT) scanning and magnetic resonance imaging (MRI), it is now possible to diagnose spinal tuberculosis at an early stage, differentiate it from other diseases, and objectively monitor the progress. In addition, sensory and motor evoked potentials provide a means of objectively documenting sensorimotor dysfunction.

Several clinical predictors of spinal tuberculosis have been evaluated but none has been found to be useful. Poor prognosis has been reported in patients with disseminated tuberculosis, paraplegia, and secondary infection of sinuses. Most of the earlier studies, however, did not employ modern chemotherapeutic regimens, MRI, and evoked potential studies. In the present communication we report the role of various clinical, MRI, and evoked potential changes in predicting the six month outcome of conservatively treated patients with Pott’s paraplegia.

**PATIENTS AND METHODS**

Our prospective study included consecutive patients with Pott’s spine and varying degree of neurological deficits, treated conservatively during 1993–2003. The diagnosis of Pott’s spine was based on clinical findings, MRI, and CT or ultrasound guided aspiration biopsy. Of 45 patients recruited, 43 completed the six months follow up and were included in the present study. We took a thorough history and the patients underwent detailed clinical evaluation. Muscle power was tested on a 0–5 MRC (Medical Research Council) scale. We tested tone, reflex and sensations of pinprick, joint position, and vibration, and noted presence of bone deformity and tenderness, soft tissue swelling, and extraspinal tuberculosis. The following investigations were done: blood count, erythrocyte sedimentation rate (ESR), serum chemistry, venereal disease research laboratory (VDRL) test, human immunodeficiency virus (HIV) serology, and radiographs of the chest and spine. Spinal MRI was performed using 2 T scanner operating at 1.5 T, and T1, T2, PD, and T1 contrast images were obtained.

We recorded tibial sensory evoked potentials (SEPs) bilaterally from Cz and L1 after stimulating the tibial nerve at the ankle. The central sensory conduction time (CSCT) was calculated by subtracting lumbar latency from the cortical. The electrical stimulator (Digitimer D180, Herts, England) was used for motor evoked potentials (MEPs) of the lower limb. The cortical stimulation was given at the vertex and the spinal stimulation at the twelfth thoracic vertebra. MEPs were recorded from the tibialis anterior (TA) by surface electrodes. Central motor conduction time to TA (CMCT-TA) was calculated by subtracting spinal latency from the cortical. We considered the evoked potentials abnormal if the cortical potentials were unrecordable or CMCT and CSCT values exceeded mean ±2.5 SD of controls. In our laboratory, the upper limit of CMCT-TA was 16.1 (12.1±1.6) ms and tibial CSCT 22.2 (17.56±1.9) ms. Patients were treated with rifampicin, isoniazid, pyrazinamide, and ethambutol and advised rest for three months. Outcome at six months was defined as poor (bedridden or dependent for activities of daily living) or good (independent for activities of daily living).

**Statistical analysis**

The independent variables possibly related to outcome were categorised as follows:

- **Sex:** male = 1, female = 2
- **Power:** grade 0–1 = 1, grades 2–3 = 2, grades >3 = 3

**Abbreviations:**
- CMCT-TA, central motor conduction time to TA
- CSCT, central sensory conduction time
- MEP, motor evoked potential
- SEP, sensory evoked potential
- TA, tibialis anterior

---

**Abbreviations:**
- CMCT-TA, central motor conduction time to TA
- CSCT, central sensory conduction time
- MEP, motor evoked potential
- SEP, sensory evoked potential
- TA, tibialis anterior
A total of 13 patients had fever and five were quadriplegic. Weakness was severe (grade 0–1) in eight patients and moderate (grades 2–3) and mild (grades >3) in 11 patients each. Power was normal in 13 patients, but they had spasticity with hyperreflexia suggesting pyramidal dysfunction. The lower limbs were spastic in 27 patients and hypotonic in one patient. In 32 patients, the tendon reflexes were exaggerated, and they were reduced in four patients and normal in seven. Loss of joint position sensations was noted in 20 patients. Sensation of pinprick was reduced in 18 patients (level: dorsal = 12, cervical = 2, lumbar = 4) and gilbus was present in 17 patients.

On MRI, a single vertebra was involved in five patients, two vertebrae in 27 and three vertebrae in 11 patients. Soft tissue shadow was present in 35 and spinal cord compression in 30 patients. Four patients had associated pulmonary and two had associated lymph node tuberculosis. CMCT-TA was not recordable in 11 and was prolonged in eight patients. SEP was not recordable in 16 and CSCT was prolonged in two patients. At six months, 29 patients had good and 14 poor recovery.

On logistic regression analysis with each prognostic variable separately, power (Z = +3.30), tone (Z = +2.37), sensory loss (Z = +2.70), level of vertebral involvement (Z = −2.30), CMCT (Z = +2.29), CSCT (Z = +3.13) and ESR (Z = −2.26) were significantly related to outcome. On multiple logistic regression analysis, the best model predicting six month outcome included power, paraplegia score, CMCT and CSCT (table 1). Figure 1 shows the relation of these variables with outcome.

### DISCUSSION

In the present study, the six month outcome of Pott’s paraplegia was best predicted by power, paraplegia score, CMCT, and CSCT (as evaluated by multiple regression analysis). Most of our patients with mild weakness recovered completely (22/24 (91.7%)) as opposed to only 25% (2/8) with severe weakness. In Pott’s paraplegia, the pathology begins in the anterior portion of the body of the vertebra, and, later, involvement of the adjacent vertebrae may result in wedge collapse. Inflammation, oedema, and necrosis may result in abscess formation, which in turn may result in spinal cord compression and focal demyelination of the ascending and descending tracts. Therefore, because of its anterolateral location, the corticospinal tract is likely to be affected more commonly and relatively early in the disease resulting in weakness. Moreover, activities of daily living and paraplegia score are mainly dependent on power. Regression of oedema, abscess, and focal demyelination following antitubercular treatment may manifest as clinical recovery, and may be more complete than bony destruction. In the present study, 71.4% (25/35) of patients with paraspinal abscesses had “good” recovery as opposed to 50% (4/8) without abscesses.

Tibial CSCT and CMCT-TA were helpful not only in objectively documenting the respective deficit but also in

![Figure 1](image-url)
predicting outcome. Of the patients with normal CSCT, 87.5% (21/24) recovered, whereas only 42.1% (8/19) with abnormal SEP recovered. SEP abnormality suggests involvement of the posterior column and perhaps indicates a more extensive involvement because most tuberculous infections begin anteriorly. All our patients had motor signs and symptoms, but only 20 had sensory deficits. The high frequency of CMCT abnormalities may be due to the larger diameter and anterolateral location of the corticospinal tract, which make it relatively more vulnerable in the early stage of Pott’s spine.

We did not come across any study in the available literature evaluating the prognostic value of MEPs and SEPs in Pott’s paraplegia with multivariate analysis. In a previous study on seven patients with Pott’s paraplegia SEP abnormalities were present in four patients and were associated with poor outcome. The prognostic role of MEP and SEP has been reported in various other spinal cord diseases such as transverse myelitis, cervical spondylisis, and subacute combined degeneration. An MRC study of Pott’s spine using 21 clinical and radiological variables failed to detect any prognostic predictor. The role of surgery in Pott’s spine is still controversial. A recent study from the USA recommended decompression and stabilisation in Pott’s spine with neurological symptoms and signs. Most of the patients in that study improved although two died. In our study, none of the patients underwent surgery, 67.4% (29/43) showed full recovery at six months, and there were no deaths.

We conclude that patients with Pott’s paraplegia with mild weakness, lower paraplegia score and normal SEP and MEP are likely to recover fully after six months of conservative treatment.
