Abstract

Objectives Assess communication between vascular neurosurgeons and their patients with unruptured cerebral aneurysms about treatment options and expected outcomes.

Methods We surveyed vascular neurosurgeons and their patients with cerebral aneurysms immediately following outpatient appointments in a neurosurgery clinic. We collected data on how well the patient understood their aneurysm treatment options, the risks of a poor outcome from various treatments, and the consensus “best” treatment. Patient and neurosurgeon responses were measured using Likert scales, multiple-choice questions, and visual analogue scales. Agreement between patient and neurosurgeon was assessed with kappa scores. The Wilcoxon sign rank test was used to compare visual analogue scale responses.

Results Forty-four patient-neurosurgeon pairs provided data. Only 61% of patient-neurosurgeon pairs agreed on the best treatment plan for the patient’s aneurysm (kappa = 0.51, moderate agreement). Among the neurosurgeons, agreement with their patients ranged from 82% (kappa=0.77, almost perfect agreement) to 52% (kappa = 0.37, fair agreement). Patients estimated much higher risks of stroke or death from surgical clipping, endovascular embolization, or no intervention over compared with the estimates offered by their neurosurgeons: surgical clipping – patient 36% vs. neurosurgeon 13% (P<0.001); endovascular embolization - patient 35% vs. neurosurgeon 19% (P=0.040); and no intervention – patient 63% vs. neurosurgeon 25% (P<0.001).

Conclusions Following consultation with a vascular neurosurgeon, many patients with cerebral aneurysms have an inaccurate understanding of their aneurysm treatment plan, and an exaggerated sense of the risks of aneurysmal disease and treatment.
There are numerous treatment options for patients with unsecured cerebral aneurysms, including surgical clipping, endovascular embolization, no intervention, serial imaging, or combinations of the above. During the process of clinical decision-making, neurosurgeons are the healthcare providers most often faced with the task of informing patients with cerebral aneurysms about their aneurysms and their treatment options. Informing patients about complex medical problems and treatments can be challenging, and despite the best efforts of the physician, patient comprehension is often imperfect. Most patients prefer to be informed about available treatment options and associated risks, and such information generally improves compliance with the treatment plan and treatment outcomes without increasing anxiety. In contrast to the almost universal desire for information, patients vary in their desire to participate in decision-making – younger patients tend to prefer more active involvement, while older patients often prefer a more passive role.

To obtain a better understanding of communication between patients with cerebral aneurysms and their neurosurgeons, we studied patients and their neurosurgeons in a vascular neurosurgery clinic. We administered surveys immediately following clinic visits to assess what information had passed between neurosurgeons and their patients about the natural history, treatment options, and expected outcomes of cerebral aneurysms. We then compared responses between patients and their neurosurgeons for insights into communication about this complex topic.

Methods

Study Population

As part of a study on quality of life in patients with cerebral aneurysms, between June 2001 and February 2004 we surveyed patients and their treating neurosurgeons in neurosurgical clinics at the University of Pittsburgh Medical Center. Informed consent was obtained from all patients prior to data acquisition, and the protocol was approved by the Institutional Review Boards of the University of
Pittsburgh and Yale University. Using structured interviews, surveys, and medical record extractions, we collected data on demographics, education, cognitive function using the Mini Mental State Exam (MMSE), medical history, habits, and aneurysm characteristics and treatments. Immediately following their appointment with a vascular neurosurgeon, subjects with an unsecured aneurysm (whether or not previous treated) were given a one-page written questionnaire about aneurysm natural history, treatment options, treatment decisions, and expected outcomes. The treating neurosurgeon was asked to complete a similar questionnaire. Three vascular neurosurgeons participated in this study - one was also fellowship-trained in interventional neuroradiology.

**Questionnaire Design**

The questionnaires asked patients and neurosurgeons to rate: 1) the patient’s understanding of treatment options, 2) the “best” treatment as agreed upon by the patient and neurosurgeon, and 3) the risk of stroke or death from attempted treatment or the future risk of death and stroke with no intervention (Appendix 1). We used 6-point Likert scales ranging from “strongly agree” to “strongly disagree” to assess the appropriateness of various treatment options and how well the patient understood them. Patients and neurosurgeons were next asked to specify which treatment option they had agreed was best for that patient. Finally, patients and neurosurgeons marked 10 cm horizontal visual analogue scales (VAS) to indicate their estimate of the risk (0-100%) of stroke or death for the patient from surgical clipping and endovascular embolization, and cumulative risk of stroke or death over the next 20 years with no aneurysm treatment intervention.

**Data Analysis**

Demographics, education, cognitive function, medical history, habits, and aneurysm characteristics and treatments were tabulated, and medians, quartiles, means, and standard deviations were calculated for continuous variables. Likert scale responses were collapsed into three categories: agree (strongly agree, moderately agree), unsure (mildly agree, mildly disagree), and disagree
Communication with Cerebral Aneurysm Patients

King et. al

Paired patient-neurosurgeon Likert scale responses and consensus treatment responses were compared using unweighted kappa scores. Kappa scores assess how closely two raters agree beyond that expected from chance alone, and quantify agreement as follows: 0-0.20, slight agreement; 0.21-0.40, fair agreement; 0.41-0.60, moderate agreement; 0.61-0.80, substantial agreement; and 0.81-1.00, almost perfect agreement.9 In a secondary analysis of paired patient-neurosurgeon responses, we combined the options that did not involve immediate action and that might be confused by patients (“leaving it alone” and “think about it more and decide later”). Paired patient-neurosurgeon VAS responses were compared using the Wilcoxon signed rank test. The characteristics of patient respondents and non-respondents were compared using the Wilcoxon sign rank test. Differences in responses across the neurosurgeons were assessed with the Kruskal-Wallis test. Results were formatted to preserve the anonymity of the neurosurgeons. Two tailed P values <0.05 were considered significant.

Results

Study Population

One hundred and twenty-two patients with one or more unsecured aneurysms consented to participate in the research study. Seventy-four patients completed crucial elements of the post-appointment questionnaire, neurosurgeons completed the questionnaire for 73 patient visits, and the resulting 44 paired patient-neurosurgeon responses are the basis for this analysis. Data collection deficiencies were caused by refusal to complete surveys because of lack of interest or time constraints, illegible written responses on survey forms, or scheduling conflicts that prevented research staff from administering the survey forms. The 44 analyzable patients were predominantly female (75%) and Caucasian (93%) with a mean (± SD) age of 56.9 ± 12.5 years (Table 1.). Forty-three percent of patients had multiple aneurysms, 87% of aneurysms were located in the anterior circulation, 30% had a
history of subarachnoid hemorrhage (SAH), and 34% had undergone a previous attempt at aneurysm obliteration. There were no significant differences between non-respondents and patients included in the analysis with respect to age, sex, race, education, cognitive function, smoking, hypertension, number of aneurysms, aneurysm locations, history of subarachnoid hemorrhage, or previous aneurysm treatment (for all, P>0.274). The patient populations of the three neurosurgeons were similar with respect to demographics, education, cognitive status, hypertension, past cigarette use, number of aneurysms, and previous aneurysm treatment (for all, P>0.102). One neurosurgeon had more patients who currently smoked cigarettes (P=0.005); one neurosurgeon had a greater proportion of patients with posterior circulation aneurysms (P=0.026).

Agreement was surprisingly low when patients and neurosurgeons were asked to select what treatment they had agreed upon together (Figure 1). Overall, only 61% of patient neurosurgeon pairs agreed on the treatment plan (kappa = 0.51, moderate agreement). There were large differences between how closely each neurosurgeon and their patients agreed on the consensus treatment plan. Concordance for the three neurosurgeons ranged from a high of 82% agreement (kappa = 0.77, substantial agreement), to 67% agreement (kappa = 0.52, moderate agreement), to 52% agreement (kappa = 0.37, fair agreement). In the secondary analysis adjusting for possible patient confusion among similar treatment options, the 64% agreement (kappa = 0.54, moderate improvement) was only slightly improved compared with the baseline analysis. Patients with a high school diploma showed better agreement with their neurosurgeon (kappa=0.56, moderate agreement) than patients with less education (kappa=0.38, fair agreement). When asked to focus on a particular treatment (e.g., surgical clipping), patients and neurosurgeons were in agreement from 49% - 60% of the time about the appropriateness of each treatment plan, with the corresponding kappa scores in the slight to fair agreement range (Table 2).
Patients estimated much higher risks of stroke or death from surgical clipping, endovascular embolization, or no intervention compared with the estimates offered by their neurosurgeons (Figure 2). The mean estimates of the risk of stroke or death from surgical clipping were: patient 36% vs. neurosurgeon 13% (P<0.001). The mean estimates of the risk of stroke or death from endovascular embolization were: patient 35% vs. neurosurgeon 19% (P=0.040). The mean estimates of the risk of stroke or death over the next 20 years without any intervention were: patient 63% vs. neurosurgeon 25% (P<0.001).

**Discussion**

Cerebral aneurysms are a potentially devastating disease requiring consideration of complex information by neurosurgeons and patients before arriving at a treatment plan. There is no precise algorithm for selecting the “best” treatment plan, and several treatment options may be equally suitable. Clinical decision-making requires the consideration of multiple factors, including aneurysm characteristics, the skill set and experience of the neurosurgeon, and patient preferences. We surveyed patients with cerebral aneurysms and their neurosurgeons following neurosurgery clinic appointments to obtain information on how well neurosurgeons communicated with their patients about treatment options, expected outcomes, and the treatment plan. In approximately 40% of encounters, the patient and neurosurgeon disagreed about which aneurysm treatment option was the best. In addition, patients consistently over-estimated the stroke and death risks from an untreated aneurysm or the risks from surgical or endovascular treatment by a factor of 2-3 compared to risk estimates offered by their neurosurgeon.

Most reports of patient-physician communication have studied encounters between patients and primary care physicians, where the emphasis is on obtaining information from the patient. Surgical consultations are fundamentally different - surgeons usually do most of the talking, focusing on patient education and counseling about treatment options.\textsuperscript{10,11} The literature is sparse on communication
between surgeons and their patients. A study of surgeons and their patients with breast cancer found high rates of agreement on the choice of surgical treatment (88%). However, the patients were presented with only two treatment options (lumpectomy and mastectomy), compared with the six options presented to our patients with aneurysms (surgical clipping, endovascular embolization, combined surgery and endovascular embolization, serial imaging, no intervention, defer decision). The need to discuss and consider a greater number of treatment options may explain the relatively poorer communication seen in our study. Given the role of surgical consultant as patient educator and counselor, our goal was to measure how well the neurosurgeon had conveyed crucial information to the patient about aneurysm treatment options, treatment risks, and expected outcomes.

Our data further indicate that vascular neurosurgeons and patients often do not recognize when there is a communication problem. Both parties thought that the patient understood their treatment options and knew the best treatment option, yet approximately 40% of patient-neurosurgeon pairs disagreed about the consensus treatment plan. One would hope that the vast majority of patients would understand the plan for their aneurysm treatment immediately after walking out of their doctor’s office, yet apparently this was not the case. Consistent with the inter-physician variability seen in other studies, we found substantial variation among the neurosurgeons in their ability to communicate the treatment plan to the patient successfully.

The patient responses indicate that most patients see aneurysms and aneurysm treatments as quite dangerous. Compared with their neurosurgeons, patients overestimated the risks of surgical treatment, endovascular treatment, and the untreated natural history of their aneurysm by a factor of 2-3. The mean patient risk estimates of stroke or death related to their aneurysm were impressively high: 36% for surgical clipping, 35% for endovascular embolization, and 63% for the untreated natural history. Many patients have difficulty understanding probabilities and risks, tending to inflate large risks and to minimize smaller risks. If patients perceived that the chances of a poor aneurysm
outcome are high, then we would expect their numeric risk estimates to be elevated. Problems with numeracy may also contribute to misunderstanding.\textsuperscript{14,15} For example, many patients may not have had a good understanding of the annual rate of rupture of an unsecured aneurysm, let alone the cumulative long-term risks. The shock of recently learning the details about the dangers of aneurysms and aneurysm treatments from the neurosurgeon may also have contributed to these elevated risk estimates.

Compared to their neurosurgeons, patients perceive that aneurysm natural history and treatment is 2-3 fold riskier. The outcomes estimates of the patients and neurosurgeons were doubtless influenced by multiple factors, including knowledge of aneurysm natural history and treatments; attitudes towards risk, disease, surgery, and death; and the effectiveness of communication between neurosurgeon and patient. All of the neurosurgeons considered aneurysms and aneurysm treatments less dangerous than their patients did, however, one of the neurosurgeons consistently gave the lowest mean risk estimates for surgical clipping, endovascular embolization, and the untreated natural history. The lower estimates may reflect differences in the neurosurgeon’s patient population and/or a more sanguine view of aneurysm disease and treatment.

The difficulties of communication between physicians and patients and the challenges of shared decision-making have been the subject of several investigations. Some educational interventions aimed at improving the communication skills of practicing physicians have been successful,\textsuperscript{16,17} but others have met with less promising results.\textsuperscript{18,19} One solution may be to teach better communication skills during medical school.\textsuperscript{20} Another approach is the use of computer technology to impart information to patients about their disease and treatment options. Computerized videodisc programs have shown benefit in educating patients with back pain,\textsuperscript{21} benign prostatic hypertrophy,\textsuperscript{22,23} menopausal symptoms,\textsuperscript{5} and ischemic heart disease.\textsuperscript{24} Perhaps similar decision-aids could be developed for patients with cerebral aneurysms, improving communication and patient decision-making.
While our results are both intriguing and consistent with research on other specialties, this study on communication between vascular neurosurgeons and their patients has two major limitations. First, the survey response rate was relatively low, thus the study sample may not have been representative of the aneurysm patient population at our institution. A thorough comparison of respondents and non-respondents found no differences in demographics, education, cognitive function, habits, medical history, or aneurysm characteristics and treatments. Nonetheless, unmeasured differences in the study population may have biased the results. Second, our single-site study may not be generalizable to other institutions, neurosurgeons, or aneurysm patient populations. Despite these shortcomings, our results are worthy of consideration and provocative enough to merit further investigation through validation studies performed at other institutions utilizing a broader selection of neurosurgeons.
