Short report

Non-paralytic motor disturbances and speech disorders: the role of the supplementary motor area

HJ GELMERS

From the Department of Neurology, Pr Irene Ziekenhuis, Almelo, The Netherlands

SUMMARY A right-handed patient with a lesion demonstrated by CT to involve the right medial frontal cortex is described. He exhibited a strong contralateral grasp reflex, motor perseveration and the presence of purposeful movements that appeared to be dissociated from conscious volition. In addition, there was a disorder of speech consisting of a lack of spontaneous speech production, with preserved ability to imitate. It is suggested that these disorders are due to damage to the supplementary motor area.

Experimental studies in man¹ indicate that there are a number of cortical fields involved in motor control, among which is the supplementary motor area. Although its functional distinctiveness has been demonstrated, there are few descriptions of the results of supplementary motor area damage.^{3 5 12 13} The purpose of this case history is to describe the clinical symptoms caused by a lesion involving the right medial frontal cortex and to outline the "supplementary motor area-syndrome".

Case history

A 69-year-old right-handed man had sudden onset of difficulty in speaking, together with weakness of the left leg. Examination on admission showed him to be awake, alert and oriented. He had a mild left-sided lower facial weakness at rest and on volition, with a striking weakness after laughing. There was total paralysis of the left leg. Although the left arm showed a global inertia and no spontaneous movements, there was no paresis. The patient found it an immense effort to move. When he moved, the movements were correct but slow and deliberate. A strong grasp reflex was noted in the left hand. Tendon reflexes were exaggerated on the left and plantar responses were extensor on the left and equivocal on the right. Visual fields and ocular movements were full. Pinprick and vibratory sensation was normal as were detection of passive

movements and identification of palpated objects. The patient did not initiate conversation. He spoke very haltingly in reply to questions. The responses were characterised by a great deal of difficulty in initiation. Comprehension of speech was good, as was the ability to imitate complex phrases sentences. There were no localising phenomena indicating parietal lobe damage; the interpretation of body-perception was normal. Computed tomograms demonstrated an area of increased density involving the right medial frontal cortex (2nd day after onset of symptoms) (fig). Ten days after onset there was still a strong grasp reflex in the left arm. The left leg had improved in strength, but remained weak. The patient was observed to reach out spontaneously with the left arm and then would not be able to release his grip voluntarily. He began to persevere with his left arm when using a knife and fork during meals, or when handling a haircomb or an electrical razor. This motor perseveration was inhibited to some extent by concentrated effort. After five weeks the patient began to walk unaided, but he still displayed motor perseveration of the left arm. This phenomenon was indeed perseveration and not tonic innervation or an inability to release objects on account of the grasp reflex.

Discussion

This patient displayed a strong grasp reflex of the left hand initially preceded by a global inertia. He was observed to have motor perseveration (inappropriate repetition of a simple movement) of the left hand. Later it was noted that apparently purposeful movements appeared to be occurring independent of conscious volitional control. Additionally, the patient exhibited a speech disorder, consisting of a lack of spontaneous speech with preserved

Fig Selection of slices from a complete set of CT-scans. The infraventricular (not depicted) and low ventricular (A) slices were normal. The high ventricular slice (B) demonstrated an area of increased density involving the medial frontal area of the right hemisphere. In the supraventricular slices (C, D) the extension of the increased area is shown (the lesion is for reasons of clarity outlined in black ink).

ability to repeat. CT showed a lesion involving the right medial frontal cortex.

A patient with some similar features has been published,² who suffered an infarction of the medial frontal cortex due to occlusion of the left pericallosal artery. This patient had spontaneous grasping together with motor perseveration of the right hand. He too was unable to inhibit these movements, although he was fully aware of them. The ability to execute new movements was retained. Others³ have described global akinesia of the right arm in patients with lesions involving the left medial frontal cortex. All these motor phenomena were observed in our patient. More widespread dissociative psychomotor phenomena, including the "alien hand sign" and "intermanual conflict" as observed in patients the first weeks following section of the corpus callosum for intractable epilepsy,⁴ were not seen in our patient. This is contrary to other observers⁵ who, in patients with medial frontal cortex infarction, noted that one of the hands behaved in a way which the patient found "alien" or at least uncooperative.

Two functional zones on the medial surface of the frontal lobes, damage to which may be implicated in the appearance of motor disturbance, as well as the

speech disorder, are the supplementary motor area and the cingulate cortex. Penfield and Jasper¹ reported that stimulation of the supplementary motor area produced vocalisation, speech arrest, complex coordinated or repetitive movements usually appearing in the contralateral arm and arrest or slowing of voluntary action following which it was noted that the patient was "usually puzzled by his inability to execute" the action he had intended. Continuous electrical stimulation of anterior cingulate cortex in epileptic patients is followed by complex, highly integrated forms of motor behaviour most often in the contralateral arm.⁶ Recently, regional blood flow studies in man have demonstrated bilateral activation of supplementary motor area in association with various complex movements of the extremities,^{7,8} as well as with speech.^{9,10} From these studies it has been suggested that the supplementary motor area is involved in the assembly and execution of time-ordered sequences of motor instructions.¹¹

Our patient also exhibited a speech disorder, consisting of a lack of spontaneous speech production, with preserved ability to imitate. This type of speech disturbance is often designed as transcortical motor aphasia¹² and has been described in patients who sustained damage to the left medial frontal cortex.^{5,12,13} Although similar disturbances of speech of patients have been recorded by others,³ no mention was made of the site of the involving mediofrontal lesion. Since the lesion in our patients was localised in the right hemisphere, it is best not to describe this speech disorder as an "aphasia". Moreover, it covers the recently proposed term "transcortical motor aprosodia".¹⁴

There seems now sufficient clinical and experimental evidence to conclude that lesions of the medial frontal parts of the hemisphere, including the supplementary motor area, gives rise to non-paralytic motor and speech disturbances.
