SUMMARY Data from ten patients with complex partial seizures who underwent positron emission tomography using the 15-0 inhalation technique are presented. Decreased flow and metabolism are noted in the hemisphere ipsilateral to the EEG focus, but, in patients with unilateral foci, bilateral changes in temporal cortex are detected. Other areas maximally affected include the basal ganglia, and the cerebellum. The possible role of anticonvulsant drugs in these findings is discussed.

Several methods have been employed to study cerebral blood flow and metabolism in epilepsy. Recently Kuhl and co-workers¹ have reported studies with positron emission tomography using the 18-fluoro-deoxy-glucose technique to assess metabolism, and have demonstrated focal decreases of glucose uptake during the interictal period in partial epilepsy. In contrast, during the ictus, increases are noted in the same areas, in keeping with the experimental literature that during seizures oxygen consumption, cerebral blood flow and glucose metabolism increase significantly.²

In this study we report preliminary data obtained using a positron emission scanner, and the oxygen 15 inhalation technique developed at the Hammersmith Hospital,³ in patients with partial seizures. The studies were all carried out interictally, and the results of regional cerebral blood flow (rCBF), regional oxygen metabolism (rCMRO₂) and the regional oxygen extraction ratio (rOER), defined as the relationship between blood flow and oxygen utilization³ are given.

Materials and methods

Ten patients with complex partial seizures were investigated. Initially they were selected because they demon-

strated on clinical examination, and had on the EEG, evidence of a temporal lobe focus. In some patients secondary generalisation was known to occur, but the predominant seizure was partial and no patient was examined who had a generalised seizure in the month prior to the scans. A history of epilepsy was present for at least 15 years in all patients. Five had a right sided focus, in three minor abnormalities but no spikes being seen in the contralateral recordings, four a left sided focus and one bilateral independent abnormalities. Basic biographical information is given in table 1. There were six males and four females with a mean age of 31.5 years (range 19-51). Their IQ was within the normal range (mean 97.1). One patient had cerebellar inco-ordination. All patients had received polytherapy with anticonvulsants, but one patient had no drugs for one year prior to the scan. Conventional CT scans were performed in all patients and were regarded as normal in eight, two showing minor cortical atrophy. For comparison, ten positron scans from age matched normal volunteers were used (mean age 30.5, range 24-49).

The methodology of the scan procedure was as follows. Oxygen-15 was produced by a cyclotron ($t_{1/2} = 2.1$ m), and during continuous sequential inhalation by the subject of 15-0 labelled carbon dioxide and oxygen, a series of transaxial emission tomograms was taken by a positron emission tomograph (EGG and ORTEC-ECATIIR). In most cases four cuts were examined at OM + 2, + 4, + 6, + 8 cm. All emission data were corrected for attenuation by the corresponding transmission scans, and tracer equations which relate steady state measurements to tissue blood flow and oxygen extraction ratios were used to calculate absolute quantitative values of rCBF, rCMRO₂, and rOER (for full details of the method see Frackowiak *et al*³).

Following a computer print-out of the quantitative data, 2.5 cm² regions of interest (ROI) were chosen corresponding to the frontal, temporal, posterior temporal and occipi-

Table 1 Clinical data of the epileptic patients

Patients		Type of seizures	Neurological examination	Site of focus (EEG)	CT scan	Frequency of partial seizures at the time of the scan (per month)
ECAT n°	Age (yr)					
170	19	CPS†	normal	left	normal	30
224	31	CPS	normal	right	normal	30
226	50	CPS†	normal	right	normal	0
298	22	CPS†	normal	right	normal	8
313	46	CPS†	normal	bilateral	cortical atrophy	3
322	36	CPS†	normal	left	normal	1
331	25	CPS‡	cerebellar incoordination	right	normal	1
341	29	CPS†	normal	right	normal	0
355	22	CPS	normal	left	normal	4
335	35	CPS†	normal	left	frontal atrophy	120

*CPS = complex partial seizures.
†CPS = secondary generalisation known to occur at some time.
‡CPS = no anticonvulsant drugs.

Fig 1 Showing regions of interest in (a) frontal, temporal and occipital lobes; and (b) temporal cortex, examined at slice OM + 4.

tal regions on two slices at OM + 4 and OM + 6 (Fig 1). A cerebellar region was chosen on the OM + 2 slice. Additional areas of 1.5 cm² were analysed in the temporal cortex and basal ganglia of the patients. Statistical analysis, comparing patients with epilepsy to normal subjects was by Student's *t* test.

Results

The mean hemisphere values, assessed by taking the values from both hemispheres at the OM + 4 slice from frontal, temporal, parietal and occipital areas are shown in table 2. Patients with epilepsy had an 18% decrease of both rCBF and rCMRO₂, compared with controls.

Regional analysis of the data from frontal, temporal, posterior temporal and occipital areas are shown in table 3. The posterior temporal areas, temporal lobe, and temporal cortex values are significantly lower in the epileptic patients for rCMRO₂. Similar but less significant changes are noted for the rCBF. Values for occipital lobe and frontal lobe are decreased in the epileptic group but with the exception of the rCMRO₂ in the frontal lobes, differences do not reach levels of significance. Basal ganglia values are also significantly diminished in the epileptic group (3.5 ml O₂/100 ml/m rCMRO₂, 38.6 ml/100 ml/m rCBF). The only significant alteration of the rOER was in the temporal cortex (0.63 *p* < 0.01).

Table 2 Mean hemispheric values of subjects with temporal lobe epilepsy

	Epileptics	Normals	%	<i>p</i>
CMRO ₂	3.6 ± 0.89	4.25 ± 0.91	-18	<0.001
CBF	38.2 ± 9.8	45.1 ± 12.6	-18	<0.05
OER	0.52 ± 0.09	0.05 ± 0.14	+4	NS

Values from both hemispheres at OM + 4 slice: frontal, temporal parietal and occipital area of 2.5 cm².

Table 3 Mean $CMRO_2$, and CBF and OER for various brain regions ipsilateral to the side of the EEG focus (N = 10)

	Epileptics $rCMRO_2$	Normals	Epileptics $rCBF$	Normals	Epileptics $rOER$	Normal
Frontal lobe	3.3 ± 0.7	3.9 ± 0.7*	39.6 ± 11.8	41.9 ± 8.7	0.50 ± 0.11	0.50 ± 0.10
Temporal lobe	3.4 ± 0.3	4.1 ± 0.8†	37.8 ± 7.8	46.3 ± 14.7	0.50 ± 0.08	0.49 ± 0.09

* $p < 0.05$

† $p < 0.01$ t test

‡ $p < 0.001$

Values of the regions in patients chosen at OM + 4 from the affected hemisphere (2.5 cm²), including temporal cortex and basal ganglia (1.5 cm²). Cerebellum measurements (2.5 cm²) taken at OM + 2. Figures are in ml/100ml/m.

Fig 2 Values of $rCMRO_2$, $rCBF$ and $rOER$ in the cerebellum. Patients and non-epileptic controls (* $p < 0.001$: t test).

Of the nine patients with a unilateral focus, temporal cortex values from the side ipsilateral and contralateral to the focus have been examined separately. There was a lower figure recorded on the side ipsilateral to the focus ($CBF-7.6\%$ ($p < 0.05$), $rCMRO_2 - 4.8\%$ (NS)), which was still present in those six patients with exclusively unilateral abnormalities on the surface EEG. However, compared to controls, even values of the contralateral temporal cortex are diminished. ($rCBF 37.8 \pm 11.9$; $rCMRO_2 3.6 \pm 0.6$). The significant difference for the $rOER$ however was not recorded contralaterally. At the level OM + 6, the only significant differences noted

were a lowered $rCMRO_2$ and $rCBF$ in the temporal lobes ipsilaterally. (3.6 ± 0.6 $p < 0.05$, and 38.1 ± 7.2 $p < 0.05$ respectively). In the age matched controls, no significant differences were noted between the values of the right and left hemispheres. In the cerebellum, $rCBF$ and $rCMRO_2$ were significantly decreased in the epileptic patients (31% and 36% respectively, $p < 0.001$) (Fig 2). No differences were seen between the hemisphere contralateral and ipsilateral to the focus. The values of $rCMRO_2$ and $rCBF$ for the cerebellum in the patient with clinical cerebellar inco-ordination were 2.8 ml/100 ml/m and 23 ml/100 ml/m respectively.

Discussion

In this study of rCMRO₂ and rCBF, using positron emission tomography, significant changes have been shown interictally in patients with complex partial seizures. While the hemisphere containing the abnormal focus shows the more marked changes, particularly with respect to rCMRO₂, the contralateral hemisphere is also abnormal with respect to normal aged matched controls. Sakai *et al*⁴, using xenon¹³³ inhalation to measure rCBF also noted contralateral changes in individual patients with partial epilepsy during activation procedures, and clearly such findings have relevance for the possibility of the development of a mirror focus.

Our data stand in contrast to those of Kuhl *et al*¹ who, using 18-fluoro-2-deoxy-glucose in patients with partial epilepsy, reported focal areas of decreased CMRglu which corresponded to EEG spike foci, but noted the results in the contralateral hemisphere to be "very similar to the distribution found in the normal subjects". In their report, however, two of their seven controls were under 6 years old. Each of our patients was matched for age as closely as possible to a control, and as little data is available as yet on children with epilepsy, the discrepancy between results may be related to suitability of controls in different studies. An alternative explanation may have been patient selection. In this series, patients were referred for positron emission tomography scans if they had a well defined focus on the EEG, although clinically four in this series had psychosis. Many of the patients from the studies of Kuhl *et al* were being investigated for possible temporal lobectomy, and may therefore be expected to show more regionally defined pathology. Indeed, six of their sample underwent lobectomy and all had pathological lesions in the resected specimen. Interestingly they noted that in these patients "the extent of the metabolic deficit was larger than the extent of the structural damage found at pathological evaluation".

In our regional analysis of the data, the most severely affected areas are in the temporal cortex, especially ipsilateral to the focus, central grey areas and the area defined as the posterior temporal lobe. Differences are far less for the occipital and frontal lobes. Decreased rCBF and rCMRO₂ in the ipsilateral temporal grey matter with the suggestion of a high rOER suggest that here, at the site of the focus the reserve of oxygen supply is diminished and the tissue metabolic requirements are high, even interictally. The consequences of this for the development of further cell damage following seizures can, at the present time be only speculative. Nevertheless such data may suggest an increased vulnerability of

neurons in the region to decreased perfusion or oxygenisation of the arterial blood during generalised seizure activity.

One of the most interesting findings is the marked disturbance of flow and metabolism seen in the cerebellar hemispheres. This affects both sides and is coupled. Cerebellar atrophy is a well described finding in epilepsy, and has been a subject of controversy with regard to its pathogenesis. While some suggest, based especially on animal data, that it occurs secondary to seizures and a resulting anoxia,⁵ other authors relate this finding to the ingestion of phenytoin.⁶ While six of our patients were on phenytoin, one was on no therapy and two were on carbamazepine monotherapy. The patient with cerebellar signs clinically was free from drugs, but did have very low values of cerebellar CBF and CMRO₂. The mean values of the patients on carbamazepine were 4.4 (CMRO₂) and 40.5 (CBF), higher than the group mean for the CMRO₂. Clearly further studies, especially examining drug free patients, are required, as well as investigations on patients with other forms of partial and generalised epilepsy. The findings of cerebellar changes in patients without detectable lesions on conventional CT scans needs further investigation, since data from animal literature⁴ showing increased cerebellar blood flow during convulsions, the demonstration of crossed cerebellar diaschisis following strokes⁷ and the data mentioned above, suggest that cerebellar involvement in epilepsy may be more substantial than previously suspected.
