Short report

Visual, cortical somatosensory and brainstem auditory evoked potentials following incidental irradiation of the rhombencephalon

SUMMARY Visual, cortical somatosensory and brainstem auditory evoked potentials were recorded before incidental irradiation of the rhombencephalon and at 11 weeks and eight months after completion of treatment. No patient experienced neurological symptoms during this period. No consistent changes in evoked potentials were found. The failure to demonstrate subclinical radiation-induced demyelination suggests either that the syndrome of early-delayed radiation rhombencephalopathy occurs in an idiosyncratic manner, or that any subclinical lesions are not detectable by serial evoked potential recordings.

The syndrome of early-delayed radiation rhombencephalopathy has been reported in five patients.¹⁻³ Each received maximal tumour doses of about 5500 rads to tumours in or around the middle ear. In four patients, the dose fractionation and field parameters were similar and a comparable dose of radiation was delivered to the rhombencephalon: in the other patient the fractionation and field parameters were not specified. The clinical features started two to three months after completion of radiotherapy and consisted of nausea, vomiting, ataxia, dysarthria, cranial nerve palsies, internuclear ophthalmoplegia and signs of corticospinal tract involvement. Three patients made a complete or partial recovery but two died within a month of onset of the illness. The necropsy^{2,4} of these patients revealed plaques of demyelination similar to those found in multiple sclerosis but limited to the volume of brainstem irradiated.

A demyelinating pathogenesis for early-delayed

radiation rhombencephalopathy is suggested by the necropsy findings and by the particular sensitivity of oligodendrocytes to radiation.⁵ The delay between radiation and the onset of the rhombencephalopathy accords well with the myelin turnover time of between five weeks and two months.⁶ The similarity of the clinical features of early-delayed radiation rhombencephalopathy to those of multiple sclerosis also is suggestive of a demyelinating pathogenesis.

Evoked potential studies have demonstrated both overt and subclinical demyelination in multiple sclerosis⁷ and similar findings might be expected following radiation-induced demyelination. We have therefore studied the visual, cortical somatosensory and brainstem auditory evoked potentials (VEP, SEP and BAEP respectively) in five patients who had received incidental radiation to their nervous system in similar doses to the reported cases of early-delayed radiation rhombencephalopathy.

Patients and methods

Five patients were studied (table 1). The tumours were irradiated by anterior-oblique and posterior-oblique fields using Cobalt-60 gamma radiation with beam trimmers (Patients 2, 4, 5) or 4MV XRs (Patients 1, 3). The isodose treatment plan of Patients 1, 2 and 3 were similar to the

Table 1 Patients and radiation details

Patient	Sex	Age (yr)	Tumour	Fraction Dose (rads)	Fraction Number	Duration of treatment (days)	TDF Number	Mean dose to brainstem (rads)
1	F	61	Glomus jugulare	200	25	35	82	2429
2	F	69	Glomus jugulare	200	25	35	82	2222
3	M	54	Glomus jugulare	200	25	35	82	2350
4	M	68	Middle ear carcinoma	400	10	24	88	2044
5	M	68	Parotid adenocarcinoma	300	15	22	92	1850

illustrated plan in reference 3. The mean brainstem dose and the time-dose-fractionation number have been calculated for each patient.⁸

Evoked potentials were recorded before radiotherapy and at 11 weeks and eight months after completion of radiotherapy. Patient 4 developed a bronchial carcinoma and was unable to attend for the eight month evoked potential recording. In Patients 1, 4 and 5, the BAEP ipsilateral to the tumour could not be recorded before radiotherapy owing to inflammation of the external auditory meatus. The patients were interviewed and examined each time that they attended for evoked potential recordings.

The evoked potentials were recorded by the methods of Halliday *et al.*,⁹ Cracco *et al.*¹⁰ and Starr *et al.*¹¹ Visual evoked potentials (VEPs) were generated by 128 pattern reversals of a 40' checks to each eye and recorded from an electrode 5 cm above theinion with a frontal reference (Fz). Sensory evoked potentials (SEPs) were generated by 256 electrical stimulations of the median nerve at each wrist at the motor response threshold: they were recorded from electrodes on the scalp seven centimetres lateral to the midline over the contralateral somatosensory cortex (1 cm anterior to P3, P4) with a frontal reference (Fz). Brainstem auditory evoked potentials (BAEPs) were generated by 1024 high intensity clicks at 70 db above the sensory threshold and recorded from electrodes over the ipsilateral mastoid process (A1, A2) referred to the vertex.

Results

None of the patients had symptoms or signs of early-delayed radiation rhombencephalopathy. There were no consistent changes in the serial recordings of the VEP, SEP or BAEP (table 2). In Patient 4, the VEP from each eye had grossly abnormal patterns and the P100 could not be identified; however the patterns were unchanged at 11 weeks. F tests and paired *t* tests between the measurements performed before radiation and at 11 weeks and at eight months showed no significance at the 95% level.

Discussion

The five patients studied experienced no neurological symptoms in the early-delayed period and showed no serial changes in VEP, SEP or BAEP. This indicates either that the incidental radiation did not cause subclinical demyelination or that any such demyelination is not demonstrable by these methods. The syndrome of early-delayed radiation rhombencephalopathy may occur in an idiosyncratic rather than dose-related manner: it is rare³ and the

(NR = evoked potentials not recorded)

susceptibility of just a few patients to radiation-induced demyelination may be due to an inherited diathesis or a concomitant acquired subclinical central nervous system disorder, such as multiple sclerosis or paraneoplastic neurotoxicity.

Evoked potential studies of the effects of rhombencephalic irradiation have not been previously reported. However, SEPs have been recorded following incidental spinal cord irradiation in man in order to study the rare syndrome of transient radiation myelopathy¹² and to detect subclinical radiation damage.¹³ The syndrome of transient radiation myelopathy consists of dysaesthesiae and Lhermitte's phenomenon following incidental spinal cord irradiation. It occurs during the early-delayed period and, like early-delayed radiation rhombencephalopathy, its clinical features resemble those of multiple sclerosis. It has been suggested that this early-delayed radiation myelopathy is also due to radiation-induced myelin damage, though there are no histological reports of necropsies performed during or soon after the onset of this syndrome. Lecky *et al*¹² studied six patients before, immediately after and six months after incidental spinal cord irradiation. Although two patients had transient symptoms of early-delayed radiation myelopathy, none had abnormal neurological signs and the SEPs were unchanged. Lecky *et al*¹² suggest that the putative demyelinating lesions in these patients may affect only a short segment of the spinal cord and therefore any slowing of conduction may not be detectable. The same may be true in the case of early-delayed radiation rhombencephalopathy. Dorfman *et al*¹³ found delayed SEPs in 15 patients following spinal cord irradiation compared to 15 age-matched normal controls. This effect was not proportional to the radiation dose but was inversely related to both treatment time and number of fractions. However, in contrast to our study and to that of Lecky *et al*,¹² evoked potentials were not recorded before radiotherapy: the apparent slowing of conduction in the irradiated patients compared to the controls may have been due to a neurotoxic effect of cancer, rather than an effect of the radiation itself.

We have failed to demonstrate subclinical CNS damage during the early-delayed period in patients receiving a brainstem radiation dose similar to the reported cases of early-delayed radiation rhombencephalopathy. Either the demyelination lesions of early-delayed radiation rhombencephalopathy only occur in patients with a pre-existing susceptibility or, as in the case of early-delayed radiation myelopathy¹² the lesions are not detectable by serial recordings of evoked potentials.

We thank Miss BP Longley, OBE and her staff for performing the evoked potential studies and Drs DD Barwick and NEF Cartlidge for their advice and encouragement. The equipment used for the evoked potentials was provided through a grant from the Multiple Sclerosis Society.
