SUMMARY The frequency of dementia, the clinical characteristics and the pattern of cognitive impairment were studied in 147 unselected Parkinsonian patients. Twenty-one patients (14.28%) were judged to be demented. They had a more severe and widespread cognitive deficit although they were affected particularly in those tests that already discriminated Parkinsonian patients from controls. A direct comparison of Parkinsonian dementia with other types of dementia is needed to validate the concept of subcortical dementia.

Since Charcot and Vulpian's observations¹ about the possible mental changes in Parkinson's disease, several authors have called attention to a cognitive decline in the disease.^{2,3} However, estimates of the prevalence of dementia have ranged considerably, and studies carried out since 1960 have shown a frequency ranging from 20 to 40%.⁴⁻⁸ Inconsistencies in these findings may be accounted for by several factors such as patient selection or different methods of psychometric evaluation. Several studies have described pervasive cognitive changes,⁹⁻¹¹ whereas others have disclosed more specific deficits in visual discrimination and visuospatial orientation,¹²⁻¹⁴ verbal fluency,¹⁵ memory,^{16,17} frontal lobe functions and conceptual abilities.¹⁸⁻²⁰ Mayeux suggested that there was a continuum from slight to severe intellectual impairment in Parkinson's disease² and that selective neuropsychological disorders were insufficient to diagnose dementia.

One recent paper²¹ estimated that 15% of patients displayed cognitive dysfunction compatible with dementia.

The aim of the present study was to evaluate further the frequency of dementia, the clinical characteristics and the pattern of cognitive impairment in an unselected population of Parkinsonians referred to our Centre for Extrapyrimal Disorders for diagnosis and treatment.

Patients and Methods

The series was 147 consecutive patients (69 females and 78

males) referred to the Centre for Extrapyrimal Disorders of the Istituto Neurologico "C.Besta" in a period of 16 months. Most patients were studied as out-patients. More severe cases were admitted to improve drug schedule and disease control and were evaluated as in-patients.

The diagnosis of idiopathic Parkinson's disease was established by the presence of clinical features (resting tremor, bradykinesia, rigidity and postural instability) and response to antiparkinsonian drugs. No patient had undergone surgical treatment. Patients with secondary Parkinsonism or with clinical evidence of involvement of other major neuroanatomical system (pyramidal and cerebellar signs, oculomotor abnormalities) were excluded.

The diagnosis of dementia was based on DSM-III criteria²² (see also **Results**) and was agreed upon by two examiners in each single case relying on interviews with patients and relatives. Particular care was taken to assess whether confusion, delusions and hallucinations were present and whether they could be modified by drug schedule variations. Lack of improvement of cognitive functions after dose reduction or drug withdrawal where appropriate, led to a diagnosis of dementia despite the clinical evidence of hallucinations, delusion and confusion. In general terms, an effort was made to examine patients when their treatment was optimised. Patients with transient confusional states were examined when free of psychotic symptoms. Patients experiencing significant motor fluctuations were examined during the on phase of the disease.

Clinical and psychometric examination was performed in 2 days. Disease severity was assessed according to the Columbia University Rating Scale (CURS) scored at the time of examination. Parkinsonian patients had a mean age of 60.97, SD 10 years and a mean educational level of 7.06, SD 3.78 years. Disease duration was 6.62, SD 4.49 years. Mean total CURS score was 25.01, SD 11.96.

At the time of evaluation, some patients were being treated with levodopa plus peripheral decarboxylase inhibitors alone (48 patients) or in combination with dopamine-agonists (26 subjects) or with anticholinergics (28 subjects) or with both

dopamine-agonists and anticholinergics (6 subjects). Other patients were on dopamine-agonists (21 subjects) or on anticholinergics (9 subjects). Finally, nine patients were untreated.

As regards evaluation of on-off phenomena and dyskinesia, only patients at risk for such phenomena (that is patients being treated with levodopa alone or in combination with anticholinergics or dopamine-agonists) were considered, not including therefore patients on dopamine-agonists or anticholinergics alone (table 1).

Fifty-one normal control subjects (21 females and 30 males) matched for age (59.07, SD 7.4 years) and educational level (6.72, SD 3.29 years) with no history of central nervous system disorders were drawn from the hospital records and patients' relatives and were examined during the same period.

The neuropsychological battery, described in detail elsewhere,²³ included the following tests: Set Test, a test of verbal fluency;²⁴ Short Tale Test from Randt Memory Test;²⁵ Benton's Visual Orientation Line Test, a test of visuo-spatial orientation;²⁶ Zazzo's Test, a test of attention which also requires visuo-motor abilities (measure of performance is the speed of execution);²⁷ Block Designs, a subtest of the Wechsler Adult Intelligence Scale (WAIS) which requires constructional abilities; Object Assembly another subtest of WAIS which tests visual organisation; Vocabulary and Similarities subtests of the WAIS which test verbal abilities. The scores of the tests were standardised on the means and standard deviations of the 51 control subjects which are shown in table 2.

Such transformation (Z scores) allowed a comparison between different tests and an appreciation of the different impairment of the patients in different tests.

The statistical analysis included Student's *t* test, chi square test and a univariate analysis of variance.

Finally, the percentage of Parkinsonians and demented Parkinsonian patients scoring less than 2 or 3 standard deviations was calculated.

Results

Twenty-one Parkinsonian patients (14.28%) were classified as demented according to DSM-III criteria (table 1). All demented Parkinsonian patients (PD-D) had had cognitive impairment for at least 6 months. They had social and occupational impairment due to mental but not to motor deficits. All PD-D had clinical and historical evidence of change in personality, impairment of abstraction and memory problems. No PD-D patients had aphasic, apraxic or agnosic disturbances at clinical examination.

Table 1 shows the main clinical and therapeutic characteristics of Parkinson's disease and PD-D patients. Among Parkinson's disease patients, nine were still untreated while the other 117 were on medication: 21 were on dopamine-agonists, nine were on anticholinergics, 39 were on levodopa plus a peripheral decarboxylase inhibitor (PDI) alone, 20 were on levodopa + PDI and dopamine-agonists, 22 were on levodopa + PDI and anticholinergics and finally six patients were on levodopa therapy + PDI and both dopamine-agonists and anticholinergics. The mean daily levodopa dosage was 646.01, SD 273.93 mg. PD-D subjects were all on levodopa plus a peripheral decarboxylase inhibitor alone (nine subjects) or in combination with dopamine-agonists (six subjects) or with anticholinergics (six subjects). The mean daily levodopa dosage was 741.80, SD 300.91 mg.

PD-D patients were older and had more severe disability than Parkinson's disease patients. On-off, wearing off phenomena and abnormal involuntary movements (AIMS) did not differ between groups. Psychotic side effects (hallucinations, delusions and

Table 3 Psychotic side effects in non-demented (PD) and demented (PD-D) Parkinsonian patients

<40	4	0	—
40–49	13	1	7.1
50–59	43	4	8.5
60–69	42	8	16.0
≥70	24	8	25.0

confusional states) were significantly more frequent in PD-D group (19 out of 21 patients) (table 1).

Table 3 shows the characteristics of psychotic side effects in Parkinson's disease and PD-D patients. In the Parkinson's disease group, psychotic side effects were similar to those found in the PD-D group even though less severe.

Table 4 shows the distribution of dementia according to age in our population. As it is evident, dementia was more prominent in older age groups. Psychometric evaluation could not be performed in five PD-D patients because of severe motor impairment and cognitive decline.

Table 5 shows the percentage of Parkinson's disease and PD-D patients scoring less than the controls' means minus 2 or 3 SD in different tests. Provided that in a normal population 2.5% of subjects are expected to score less than the normal mean minus 2 SD in a given test, it is evident from table 5 that Parkinson's disease patients were impaired only in Block Designs, Zazzo's Test and Benton's Test in a proportion greater than that expected. On the contrary, PD-D patients scored less than 2 SD in all tests in a proportion greater than that expected. In PD-D patients, the percentage of patients scoring less than 2 SD varied widely ranging from 6.3% in Vocabulary and Short Tale to 81.3% in Block Designs and Zazzo's Test. Block Designs proved the most sensitive test in that 62.5% of patients scored less than 3 SD. Table 6 shows a comparison of Z scores of Parkinson's disease and

PD-D in different tests. PD-D had significantly worse scores in all tests. They were especially impaired in Zazzo's Test and Block Designs.

Discussion

The frequency of dementia in our series was lower than that reported in other studies in which definite criteria for dementia were used.^{4–8} In our study the frequency was similar to the value reported by Mayeux *et al*²⁸ in 355 patients and to that predicted by Brown and Marsden²¹ in a review on the methodological aspects in the diagnosis of dementia in Parkinson's disease. Such discrepancy can be explained on the one hand by a selection bias in our study concerning patients referred to a centre for movement disorders thus including patients in whom the reasons for referral were more likely motor problems rather than intellectual decline, thus underestimating the true frequency of dementia in the general population of Parkinson's disease patients. On the other hand, the discrepancy may also be accounted for by the older age of the patients in other reports. It should be mentioned that subdivision based on the various age groups in Marttila and Rinne's series,⁶ showed the dementia frequency in different groups to be similar to ours. The frequency of dementia increases with advancing age in Parkinson-

ians as in the general population and it appears that the additional risk is relatively mild.²¹

More of the PD-D patients showed hyperkinesia and motor fluctuations than did demented Parkinsonians in other reports.^{7,29} A previous study of our group³⁰ did not show a significant difference in the prevalence of on-off phenomena and hyperkinesia in younger onset Parkinsonians than in other Parkinsonians but stressed the earlier onset of those phenomena in younger patients. A longer disease duration in our demented patients may therefore account for the higher frequency of hyperkinesia and on-off phenomena in our demented patients. In agreement with other reports,^{7,29} our PD-D patients showed greater Parkinsonian impairment as well as increased susceptibility to psychotic disturbances induced by levodopa, anticholinergics and dopamine-agonists.^{31,32}

It may be argued that the greater symptom severity of the PD-D group might be partly due to a lower mean levodopa dosage. That was not the case; the mean levodopa dosage for PD-D patients was 741·80, SD 300·91 mg, whereas mean levodopa dosage for Parkinson's disease patients was 646·01, SD $\pm$ 273·93 ($p = ns$). This supports the notion that greater disease severity accounted for greater symptom severity in PD-D and that suboptimal treatment was not the cause of the difference in symptom severity.

Moreover, none of the PD-D patients was on monotherapy with either dopamine-agonists or anticholinergics, whereas many of the Parkinson's disease patients were either on dopamine agonists alone (22 subjects) or on anticholinergics alone (nine subjects) or even still untreated (nine subjects).

With this respect it is well-known that only mildly impaired Parkinsonian patients may obtain the advantage of anticholinergics or dopamine agonists because these drugs are less effective than levodopa.

Interestingly, Parkinson's disease patients showed fewer confusional states and psychotic symptoms despite the fact that the percentage of Parkinson's disease patients treated with anticholinergics alone or in combination with levodopa was similar (31%) to that of PD-D patients (28%) treated with the association of levodopa plus anticholinergics.

An open question is whether PD-D patients have a different pattern of cognitive impairment from Parkinson's disease. Our results showed that some cognitive functions were preserved whereas others were impaired in Parkinson's disease. The percentage of Parkinson's disease scoring less than 2 SD was that expected by chance in verbal tests, memory and Object Assembly. On the contrary, Zazzo's Test and Block Designs appeared to be particularly impaired in Parkinson's disease. Such test required sustained attention and perceptual motor abilities.

The selective cognitive impairment we observed in

Parkinson's disease, is evidence against the idea of a widespread cognitive deficit in that disease.¹¹ Our results indicated that tests requiring visuo-spatial analysis and motor control were especially impaired in Parkinson's disease. Such tests have been shown to be at least partially dependent on the simple and complex motor abnormalities of Parkinson's disease.³⁶ In agreement with other reports,³³ we observed also an impairment of visuo-spatial orientation. This point remains more controversial, however.

Recently, Della Sala *et al*³⁴ and Brown and Marsden³⁵ reported no alterations of visuo-spatial abilities in Parkinson's disease. However, they based their conclusions on the study of a selected sample of Parkinsonians. In that regard, it is appropriate here to consider some methodological aspects of our present study to appreciate better the significance of our results based on the analysis of a large sample of patients. Only a small percentage of our Parkinson's disease patients had performances inferior to 2 SD of controls even in the most affected tests. Brown and Marsden, reviewing the subject matter of cognitive impairment in Parkinson's disease,³⁷ concluded that their performance was within normal limits showing only a slight impairment when compared with controls. Accordingly, the consistent variability²⁰ in cognitive performances of Parkinson's disease in different studies is probably due to a selection bias in some studies including in some series patients with global cognitive impairment who may well have been regarded as demented.

In our series, some patients appeared to be more compromised in some specific tests, as became clear when patients were classified according to the mean and SD of the controls, suggesting that those tests may have revealed general cognitive deterioration better than others. Therefore, the existence of specific cognitive deficits along with the presence in our series of patients with borderline dementia, may have accounted for the worse performance of the whole group of Parkinson's disease patients in the tests more sensitive to mental decay.

Our present study, which was descriptive in nature, did not allow the definition of subgroups³⁸ with specific alterations for instance in memory, cognitive planning or visuo-spatial deficits. However, our results in PD-D may shed some light on the characteristics of cognitive impairment in Parkinson's disease. Our PD-D showed a global cognitive decline involving all cognitive aspects. Nevertheless, the outline of their cognitive impairment followed that of Parkinson's disease. In fact, PD-D were impaired above all in perceptive visual tests and attention tests which already best discriminated Parkinson's disease from controls. This suggests that those cognitive functions already impaired in Parkinson's disease are impaired above all

because of the dementing process. The specificity of such observations, however, needs to be demonstrated by a comparison with other dementing diseases, especially Alzheimer disease. Recently, Huber *et al*¹⁹ found evidence for different patterns of cognitive involvement in demented Parkinsonian patients versus Alzheimer's patients, thus suggesting that subcortical dementia⁴⁰ is a useful concept to describe cognitive impairment in Parkinsonians. These results need confirmation since it appears that subcortical dementia is a useful concept in clinical terms but it still lacks clear-cut neuropsychological evidence.
