Short report

Somatostatin content and receptors in the cerebral cortex of depressed and control subjects

SUMMARY Somatostatin-like immunoreactivity is reduced in the cerebrospinal fluid in depression and this is presumed to reflect alterations in cerebral somatostatinergic systems. We have examined this hypothesis by measuring this immunoreactivity and somatostatin receptors in post-mortem cortical tissue from depressed patients and control subjects. There was no significant difference in the temporal and occipital cortex in somatostatin-like immunoreactivity or in somatostatin receptor affinity and binding capacity between depressed and control groups. It is concluded that there may not be an alteration of cortical somatostatin function in depression.

Somatostatin is present in both the central nervous system and peripheral tissues. It has a wide range of activities, inhibiting the secretion of many hormones, including growth hormone, and functioning as a neurotransmitter or neuromodulator.¹ These effects have led to studies on the involvement of somatostatin in psychiatric illnesses. Somatostatin concentrations in cerebrospinal fluid (CSF) have been reported to be reduced in depression.²⁻⁵ This finding is not, however, specific to depression, as reduced levels have also been noted in anorexia nervosa, schizophrenia and senile dementia.²⁻⁵ CSF somatostatin is considered to derive from brain tissue, with contributions from a variety of regions (although the relative importance of different regions has not been established³). Reduced CSF concentrations of somatostatin may be the result of reduced numbers of cerebral somatostatin-containing neurons, reduced release or an increased rate of elimination of somatostatin.

We have investigated somatostatin-like immunoreactivity (SLI) and somatostatin receptors in two cortical regions to establish whether there are changes in this system in depression.

Methods

Subjects

Depressed subjects had died of coincident physical illness while inpatients at a psychiatric hospital. A detailed description of subject selection is given by McKeith *et al.*⁶ Diagnosis was made using DSM III criteria for major depressive episode.⁷ Nine subjects were studied (six female, three male). One subject was in the depressed phase of a bipolar affective illness. In seven of these subjects there was clinical evidence of major depression within 2 weeks before death, the other two had depressed mood during this time. Seven subjects were sub-classified as having melancholia, three of these with psychotic features. Mean age was 73, 7 yr (mean, SD; range 63-84). Time interval between death and freezing of tissue (post-mortem delay) was 5-45 h (26, 13 h; mean, SD). Subjects died of natural causes, principally from vascular disease. Two subjects were drug-free (for at least a month) at the time of death, one subject was taking benzodiazepines and the remainder were taking antidepressants. A global assessment of cognitive functioning (37 item mental test score⁸) was available in most cases and was not in the range suggestive of dementia.

Control subjects had died in hospital from natural causes, principally vascular disease. Case notes were examined and subjects with a history of psychiatric illness or psychotropic medication were excluded. Seven subjects were studied (six female, one male; age 77, 6 yr; mean, SD). Post-mortem delay was 3-44 h (19, 26 h; mean, SD).

Brain dissection

The brain was removed from the skull, the left hemisphere was coronally sliced and the sections were sealed in poly-

thene, snap-frozen in arcton and stored at -70°C . Cortical grey matter was sub-dissected from the coronal slices at -10°C .

Somatostatin assay

Tissue from the temporal and occipital cortex was homogenised in 10% (w/v) 0.1 mol l^{-1} hydrochloric acid/0.005 mol l^{-1} ascorbic acid. The mixture was heated to 80°C for 10 min, centrifuged (12 000 g, 10 min) and the supernatant stored at -20°C . Prior to assay samples were thawed, re-centrifuged under identical conditions, and neutralised using 1 mol l^{-1} sodium hydroxide. Somatostatin-like immunoreactivity was measured using the radioimmunoassay method and reagents supplied by Amersham, UK. The antiserum recognised somatostatin 14, 25 and 28 (somatostatin 14 was used as standard). Minimum detectable concentration of somatostatin was 3.1 pmol l^{-1} . All samples were measured in a single assay which had a coefficient of variation of 5%. Protein was measured using the Bradford method⁹ with BSA (RIA grade, Sigma) as standard. Results were expressed as fmol somatostatin mg protein $^{-1}$.

Somatostatin receptor assay

The method used for somatostatin receptor binding was essentially that described by Whitford *et al.*¹⁰ Brain tissue was weighed, homogenised using a Teflon/glass homogeniser in 10 volumes of ice cold buffer 1 (50 mM Tris-HCl, 10, mM MgCl_2 , 2 mM EGTA and 0.32 M sucrose, pH 7.2). The homogenate was centrifuged at 1000 g for 10 min (4°C) and the supernatant re-centrifuged at 20 000 g for 30 min (4°C). The resultant pellet was resuspended in buffer 2 (50 mM Tris-HCl, 10 mM MgCl_2 , 2 mM EGTA, 0.1% w/v BSA, aprotinin (100 KIU ml^{-1}) and bacitracin (10U ml^{-1}), pH 7.2). Receptor binding was determined by incubating 0.1 nmol l^{-1} (^{125}I) Somatostatin-14 (tyr¹¹) (Amersham, 2100 Ci mmol $^{-1}$) in the presence of 0.025 to 0.8 nmol l^{-1} unlabelled somatostatin-14 with 50–100 μg membrane protein in a final incubation volume of 200 μl . The incubation was allowed to proceed for 30 min at 30°C . Non-specific binding was assessed by addition of μl mol l^{-1} unlabelled somatostatin-14. The reaction was terminated by centrifugation at 14 000 g for 3 min and the resultant pellet washed with 1 ml 50 mM Tris-HCl, 0.01% (v/v) Triton X-100, pH 7.2. The radioactivity associated with the pellets was measured in a gamma counter at 78% efficiency. Binding capacity and affinity was determined by Scatchard analysis.¹¹ The subsequent plot was found to be linear across the range of concentrations employed, indicating the presence of only one high affinity binding site under these conditions.¹⁰

Results

Results for temporal and occipital cortices are shown in the table.

SLI showed no significant difference between depressed and control subjects in either cortical region ($p > 0.05$, Student's *t* test). SLI in the temporal region was higher than in the occipital region ($p < 0.001$ for combined groups, Student's *t* test).

Somatostatin receptor affinity in depressed and control groups was not significantly different, or

Table Somatostatin concentrations, somatostatin receptor affinity (*Kd*) and somatostatin receptor binding (*Bmax*). Mean, standard deviation.

	<i>Somatostatin concentration (fmol mg⁻¹)</i>	<i>Somatostatin receptor</i>	
		<i>Kd (nmol l⁻¹)</i>	<i>(fmol mg⁻¹)</i>
<i>Temporal cortex</i>			
Depressed subjects	605, 195	0.30, 0.17	49, 24
Control subjects	400, 245	0.35, 0.20	47, 28
<i>Occipital cortex</i>			
Depressed subjects	198, 105	0.32, 0.17	35, 26
Control subjects	215, 126	0.27, 0.12	27, 12

between different brain regions ($p > 0.05$, Student's *t* test). No significant correlation was observed between age or post-mortem delay, and either SLI or receptor binding in the cortical regions studied ($p > 0.05$, Kendall's rank correlation test).

Discussion

The absence of change in either SLI or receptor status of somatostatin is evidence that this system is not altered in the occipital or temporal cortex in depression. This conclusion is supported by a previous study in the frontal cortex (using the same post-mortem subjects) where we found no difference in SLI between depressed and control subjects.¹² Similarly we have found no difference in SLI between suicide subjects ($n = 12$) (retrospectively diagnosed as having a depressive illness) and controls, ($n = 12$), in a study of frontal, motor, parietal and temporal cortex.¹³ Although the group sizes are relatively small these results suggest that there is no significant change in somatostatin in the cerebral cortices in depression and that reduced CSF concentrations are therefore unlikely to reflect an alteration in cortical somatostatin-containing systems. Altered CSF levels may be due to changes in areas such as the hypothalamus or parts of the limbic system which contain high levels of somatostatin and lie near to the ventricular system.¹⁰

These data contrast with the results described by some workers for Alzheimer-type dementia (ATD) where reduced CSF somatostatin⁵ is accompanied by reduced cortical somatostatin¹⁴ and reduced receptor binding¹⁵ in severely affected subjects. These post-mortem results are controversial and may simply reflect cell loss. Other studies of ATD subjects have not demonstrated changes in either SLI¹⁶ or high affinity somatostatin receptor density.¹⁰

While neurochemical measurements in post-mortem brain have the advantage over CSF measurements of being a more direct measure of neurotransmitter status, there are several ways such as post-mortem delay when neurotransmitters and/or receptors may be degraded. However, most peptides,

including somatostatin, appear to be stable for considerable periods after death.¹⁷ The lack of correlation between post-mortem delay and the measures of somatostatin and its receptors indicates that degradation is unlikely to be a serious problem in the present study. No effect of age was noted. However, there were insufficient drug-free subjects to allow statistical analysis of medication effects, and it would be desirable to replicate this study using drug-free subjects.

To conclude, the results of this study, and of our previous studies of other cortical regions, imply that cortical somatostatin function is unlikely to be altered in depression. However, post-mortem measurements can only provide clues to alterations in neurotransmitter activities; full assessment awaits the development of techniques for assessing their function in the living subject.

Thanks are due to Mrs H Flett for typing the manuscript. Dr Charlton was funded by the Wellcome trust.
