Smooth pursuit eye movement deficits after pontine nuclei lesions in humans

B Gaymard, C Pierrot-Deseilligny, S Rivaud, S Velut

Abstract

Eye movements were recorded electro-oculographically in four patients with basal pontine lesions, demonstrated by MRI. The most prominent eye movement abnormality observed was mild to severe impairment of smooth pursuit and optokinetic nystagmus, mainly ipsilateral to the lesion. This abnormality is thought to result from damage to the pontine nuclei, which form a crucial relay between the cerebral cortex and the cerebellum controlling smooth pursuit. Abnormalities of saccades and the vestibulo-ocular reflex in one patient are also discussed.

(*J Neurol Neurosurg Psychiatry* 1993;56:799-807)

The pontine nuclei (PN) consist of several groups of neurons in the basis pontis relaying signals from the cerebral cortex towards the cerebellum. Some of them, namely the dorso-lateral, the lateral, and the dorsomedian PN, could be specifically involved in smooth pursuit eye movements, and represent a crucial link in the corticopontine pathways mediating this eye movement.^{1,2,3} However, the location and function of the PN involved in smooth pursuit still have to be precisely determined in humans. The first human case with a selective PN lesion and including eye movement recordings was recently reported.⁴ It provided data consistent with the results of experimental lesion studies involving the dorsolateral pontine nuclei (DLPN) in the monkey. We report four patients with diverse vascular lesions affecting the basis pontis, resulting in various impairments of smooth pursuit and optokinetic nystagmus (OKN). The relation between smooth pursuit impairment and the location of the lesions is discussed.

Case reports

PATIENT 1

A 73 year old woman had been complaining for a year and a half of a right trigeminal neuralgia despite carbamazepine therapy. She thus agreed to a neurosurgical procedure, and a microvascular decompression of the fifth nerve was performed. After surgery, the patient awoke with left hemiplegia. There was no cerebellar symptoms, no sensory loss, and no diplopia. MRI showed a right pontine lesion, compatible with a haematoma (fig 1).

This lesion was located along the lateral edge of the basis pontis, and affected about two thirds of the rostrocaudal extent of the pons (fig 2). When eye movement recordings were made, one week after surgery, the left hemiplegia had not improved, though the patient was alert and cooperative.

PATIENT 2

A 59 year old woman was hospitalised after the sudden onset of right hemiplegia. On initial examination, severe right hemiplegia was observed. On the left side, strength was normal but there was dysmetria in the finger to nose test. All sensory examination was normal. MRI showed a left pontine lesion, compatible with an infarct (fig 3). A transverse section showed that the lesion affected almost all the left basis pontis, and slightly crossed the midline (fig 3A). The pontine tegmentum was spared, except for a limited part of the median structures, on which a very narrow posterior extent of the lesion impinged (fig 2). Sagittal sections clearly showed that the lesion had a short rostrocaudal extent, and consisted of a thin horizontal slice (about 5 mm) at the mid-pons level (fig 3B). MRI did not show any lesions in the superior or inferior cerebellar peduncles or in the cerebellum. Eye movement recordings were performed five months after the stroke. At that time, the motor deficit and the cerebellar syndrome persisted. The patient was alert and cooperative.

PATIENT 3

A 34 year old woman with no medical background was hospitalised after the sudden onset of pure left hemiparesis. MRI showed a lesion restricted to the basis pontis, compatible with an infarct. It was located just below the mid-pons level, along the midline, with a limited extent on the right side (fig 2). On sagittal sections, it occupied approximately 30% of the whole rostrocaudal extent of the pons. Eye movement recordings were performed one month after the stroke. At that time, there was no improvement in the motor deficit, though the patient was alert and cooperative.

PATIENT 4

A 66 year old woman with a long history of hypertension suddenly experienced isolated left hemiplegia. MRI showed a lesion compatible with an infarct, located on the right side of the brainstem, at the mid-pons level. The lesion was restricted to the basis pontis,

Figure 1 MRI of patient 1 (T_1 weighted, $TR = 500$ ms, $TE = 10$ ms) shows a right pontine lesion, compatible with a haematoma, located in the lateral part of the basis pontis, with a marked rostrocaudal extent. (A) pontomesencephalic junction, (B) upper pons, (C) mid-pons, (D) lower pons.

except on the midline where it extended slightly into the tegmentum (fig 2). On sagittal sections of the brainstem, it occupied approximately 40% of the rostrocaudal extent of the pons. Eye movements were recorded six weeks after the stroke. By this time, the motor deficit had improved moderately, and the patient was alert and cooperative.

Eye movements

For all patients, eye movements were recorded using direct current electro-oculography (EOG), with the head immobilised. Two temporal electrodes were used for horizontal eye movements, and two others were located above and below the right eye for vertical eye movements.

Figure 2 Drawing of the lesions of the four patients based on MRI scans (drawn by the authors). (A) midbrain, (B) upper pons, (C) mid-pons, (D) lower pons, an = abducens nucleus, ml = medial lemniscus, mlf = medial longitudinal fasciculus, R = right. The dorsoventral broken line passes through the peduncular PN and clearly separates the DMPN, laterally, and the DMPN, medially.

Saccades and smooth pursuit were elicited in a dimmed room with a ramp of light emitting diodes (LED), located 80 cm in front of the subject. Horizontal visually guided saccades were studied by asking the subject to look as fast as possible at a suddenly appearing 20° lateral target. Horizontal smooth pursuit was induced by asking the subject to track an LED moving sinusoidally with an amplitude of $\pm 20^\circ$, at various speeds (peak velocities of 22.5, 29, and 45°/s for patient 1, and 14.5, 22.5, 29, and 45°/s for the other patients). For each speed, smooth pursuit gain (defined as the ratio of peak eye velocity to peak stimulus velocity), was calculated for each lateral direction by averaging the gain obtained in 10 successive cycles. The calculation of smooth pursuit gain was made from the chart (speed of the chart paper 10 mm/s). Furthermore, an index of asymmetry of smooth pursuit was defined as:

$$\frac{\text{right gain} - \text{left gain}}{\text{right gain} + \text{left gain}} \times 100$$

Vertical saccades and smooth pursuit were recorded under the same conditions as for horizontal eye movements, but only qualitatively analysed.

Figure 3 MRI of patient 2 (T_1 weighted, TR = 600 ms, TE = 12 ms) shows a left pontine lesion, compatible with an infarct. (A) horizontal section at the mid-pons level. The lesion involved almost all of the left basis pontis, with slight extension, medially into the tegmentum and contralaterally. (B) sagittal section. The lesion had a limited rostrocaudal extent.

For patient 1, horizontal OKN was obtained by the manual displacement of alternate black and white stripes over a large part of the visual field. The horizontal vestibulo-ocular reflex (VOR) was studied in a dimmed room on an armchair rotating with an amplitude of $\pm 20^\circ$, without stimulation being recorded, and VOR suppression was tested by asking the patient to fixate a target rotating with the armchair. These different eye movements were analysed qualitatively.

For the other patients, OKN was elicited by vertical black and white stripes, covering 50° of the visual field and moving regularly at 10, 20, and 30°/s. The horizontal VOR was studied in complete darkness, using a chair

Figure 4 Horizontal eye movement recordings of patient 1. In figures 4, 5, and 6, rightward eye movements are represented by an upward trace, and leftward eye movements by a downward trace. (A) Saccades, with normal latency, amplitude, and velocity. (B) Smooth pursuit, saccadic bilaterally though mainly rightwards. (C) OKN, asymmetrical, with slower rightward slow phase (horizontal arrows indicate the direction of stimulation, and vertical arrows a change in the direction of stimulation). (D) VOR, normal. (E) VOR suppression, impaired bilaterally, without visible asymmetry. *e* = eye, *t* = target.

	Latency (ms)		Velocity (°/s)	
	R	L	R	L
Patient 1	300	270	402	399
Patient 2	225	240	120*	144*
Patient 3	180	200	335	340
Patient 4	228	230	355	410
First control group	237 (47)	236 (59)	327 (72)	325 (72)
Second control group	197 (30)	192 (28)	346 (60)	331 (58)

In this and all subsequent tables patients 1, 2, and 4 are compared with the first control group and patient 3 is compared with the second control group. L = left, R = right; *Outside the normal range (mean (2 SD)).

rotating at 0.25 and 0.40 Hz with a 20° amplitude on each side of the midline, under two conditions. Under the first condition, the patient was asked to fixate an earth-fixed visual target while being rotated, which tested both the VOR and smooth pursuit. Under the second condition, the visual target was turned off, but the patient was asked to imagine it while being rotated, which tested only the VOR. Ability to suppress the VOR was also studied, the patient being asked to fixate a target rotating with the armchair. Mean gains were calculated for OKN, the VOR, and VOR suppression (ratio of peak eye velocity to peak head velocity).

Two control groups, each of 10 normal subjects, were used, because patient 3 was markedly younger than the other three. The first control group had a mean age of 60 years (range: 51–67 years), and the second a mean age of 35 years (range: 25–44 years). The results of patients 1, 2, and 4 were compared with those of the first control group, and the results of patient 3 with those of the second control group.

Results

PATIENT 1

Horizontal saccades were accurate and had latency and velocity analogous to those of the first control group (fig 4A and table 1). Smooth pursuit gain was markedly decreased bilaterally, even for a low stimulus velocity (fig 4B and table 2). Furthermore, there was marked asymmetry for each speed (fig 7) with a more severe deficit for rightward smooth pursuit (fig 4B and table 2). Therefore, many catch up saccades were needed to follow the target. OKN slow phase was clearly asymmetrical, with a slower rightward slow phase (fig 4C).

The VOR was symmetrical and qualitatively normal (fig 4D). VOR suppression was impaired bilaterally, as shown by the presence of a vestibular nystagmus, even for slow rotations, without obvious qualitative right-left asymmetry (fig 4E).

Vertical saccades appeared normal, with no dysmetria. Both upward and downward smooth pursuit appeared severely impaired, being almost entirely replaced by catch up saccades.

PATIENT 2

Horizontal visually guided saccades were accurate, with latencies analogous to those of the first control group, but with markedly reduced velocities, bilaterally (fig 5A and table 1).

Smooth pursuit was impaired bilaterally (fig 5B and table 2), but predominantly towards the left side, with marked asymmetry for 14.5, 22.5 and 29°/s target velocities (fig 7). This asymmetry disappeared at higher target velocities. The OKN slow phase gain was decreased bilaterally, though more markedly leftwards (fig 5C and table 3).

Under the first condition (the patient fixating an earth-fixed target), the VOR gain was

The side of the lesion is denoted in bold. (See also the legend of Table 1.)

Figure 5 Horizontal eye movement recordings of patient 2. (A) Saccades, with normal latency and amplitude, but bilateral decreased velocity. (B) Smooth pursuit, saccadic bilaterally, mainly leftwards. (C) OKN, asymmetrical with slower leftward slow phase (horizontal arrows indicate the direction of stimulation, and the vertical arrow a change in the direction of stimulation). (D) VOR (a) under the first condition, with normal gain; (b) under the second condition, asymmetrical with normal leftward gain but increased rightward gain. (E) VOR suppression, impaired bilaterally, though mainly rightwards. e = eye, s = stimulation, t = target.

analogous to that of the control group (fig 5D and table 4). Under the second condition, rightward VOR gain increased, but leftward VOR gain was normal, resulting in significant right left asymmetry ($p < 0.001$, Student's test) (fig 5D and table 4). VOR suppression gain was impaired bilaterally, though mainly rightwards (fig 5E and table 4). The ratio of leftward gain to rightward gain was approximately 1 for the VOR under the first condition, it was 0.36 for the VOR in the second condition, and 0.35 for VOR suppression.

Vertical saccades (20° amplitude) had normal latency and accuracy. Their velocity seemed qualitatively normal (about 240°/s upwards and 245°/s downwards). Smooth pursuit was almost entirely saccadic both upwards and downwards, and velocity of vertical OKN slow phases was markedly reduced.

PATIENTS 3 AND 4

Velocity and amplitude of horizontal saccades of patient 3 (fig 6A) and patient 4 were analogous to those of the second and first control groups, respectively (table 1). Smooth pursuit was impaired, mainly at higher target velocities, slightly more ipsilaterally (fig 6B and table 2). Asymmetry was slight for targets moving at 14.5°/s, 22.5°/s, and 45°/s for patient 3, and the index of asymmetry was within the normal range for patient 4 (fig 7). Horizontal OKN was similarly impaired, with no (patient 3) (fig 6C and table 3) or slight asymmetry (patient 4) (table 3).

In both patients, the VOR was normal under both conditions, and VOR suppression was impaired, with no asymmetry (fig 6 D and E, and table 4). Vertical smooth pursuit was qualitatively mildly impaired (that is, slightly saccadic), both upwards and downwards.

Discussion

All the patients had a limited vascular lesion located in the basis pontis. Two structures, therefore, were damaged, at least partially: the corticospinal tract and the PN. The pontine tegmentum was spared in patients 1 and 3, and slightly damaged in patients 2 and 4, on the midline. The contralateral motor deficit existing in all four patients could easily be ascribed to damage to the corticospinal

Table 3 Horizontal optokinetic nystagmus (OKN) gain

tract. Impairment of smooth pursuit was probably a result of the PN lesions. We will mainly deal with this point, but abnormalities concerning the VOR and horizontal saccades in patient 2 will also be discussed briefly.

SMOOTH PURSUIT AND OPTOKINETIC NYSTAGMUS

The precise location of the different PN groups is unknown in humans. In the monkey, the PN consist of several contiguous subdivisions, classified using topographical criteria. The classification proposed by Nyby and Jansen,³ although obtained using old anatomical techniques, is still used as a reference by modern authors.^{6,7,8} They distinguish the median PN, dorsal PN, lateral PN, ventral PN, and peduncular PN, all of which are intermingled with the corticospinal tract. These nuclei extend from the pontomedullary junction to the pontopeduncular junction.⁶ The subdivisions involved in smooth pursuit have recently been investigated. The DLPN have been extensively studied and appear to control smooth pursuit. The DLPN receive afferences from ipsilateral cortical areas involved in smooth pursuit: the middle temporal (MT) and medial superior temporal (MST) areas,⁶⁻⁹ and the frontal eye field (FEF).^{3,10,11} The DLPN project to the cerebellar structures involved in smooth pursuit—that is, bilaterally to the oculomotor vermis and the fastigial nucleus, and also bilaterally but mainly contralaterally to the flocculus.^{1,12-18} Neurons in the DLPN discharge during ipsilateral or contralateral smooth pursuit.¹⁹⁻²² Microstimulations applied within the DLPN increase ipsilateral smooth pursuit velocity, but do not elicit slow eye movements if eyes are not already performing smooth pursuit.²³ It should be noted that the same fact was observed for stimulations of area MST.²⁴ Furthermore, it has been reported, in the monkey and in one patient, that a DLPN lesion results in a decrease in smooth

pursuit gain, mainly ipsilaterally.^{4,25} Other PN are also probably involved in smooth pursuit. The lateral PN (LPN) have largely similar connections to those of the DLPN, although they appear to project more heavily to the floccular region than the DLPN.^{7,8,13} A lesion restricted to the LPN in the monkey results in severe impairment of ipsilateral smooth pursuit.²⁵ Recent experimental data suggest that the dorsomedian PN (DMPN) are also probably involved in smooth pursuit.^{2,26} The DMPN receive unilateral afferences from areas MT and MST, and bilateral afferences from the FEF.^{2,11} They send efferences mainly to the vermis, bilaterally, and also to the contralateral flocculus.^{2,13,15} Cells in these nuclei discharge during smooth pursuit and, in the monkey, a lesion in this area impairs smooth pursuit.² Lastly, the nucleus reticularis tegmenti pontis (NRTP), located at the anterior part of the upper pontine tegmentum and difficult to differentiate anatomically from the nearby DMPN, also appears to be involved in smooth pursuit.² Cells in the rostral NRTP discharge during smooth pursuit,²⁷ and stimulation of the NRTP elicits slow eye movements (even if the eyes are not already performing smooth pursuit),²⁸ as does stimulation of the FEF.²⁹ The NRTP receives afferences from the FEF³⁰ and projects heavily to the flocculus and also to the vermis.^{13,14} Lastly, a lesion affecting the NRTP in the monkey results in smooth pursuit impairment.³¹ Therefore, two parallel pathways could control smooth pursuit between the cerebral cortex and the pons: the first could originate in the temporoparietal cortex (areas MT and MST), and project mainly to the DLPN and LPN, whereas the second could originate in the FEF and project mainly to the NRTP and/or the DMPN. The specific roles of these two parallel pathways in smooth pursuit remain, however, to be determined.

Smooth pursuit impairment differed between our four patients. Ipsilateral smooth

Figure 6 Horizontal eye movement recordings of patient 3. (A) Saccades, normal. (B) Smooth pursuit, mildly impaired. (C) OKN, mildly impaired (horizontal arrows indicate the direction of stimulation, and the vertical arrow a change in the direction of stimulation). (D) VOR (a) under the first condition, normal; (b) under the second condition, normal. (E) VOR suppression, slightly impaired bilaterally. e = eye, s = stimulation, t = target.

pursuit was severely impaired in patient 1, moderately impaired in patient 2, and only slightly impaired in patients 3 and 4. Smooth pursuit asymmetry was also pronounced in patient 1, less marked in patient 2, and very slight in patients 3 and 4. At first, a difference in the age of the lesions may account for different rates of recovery between the patients, especially for patient 2, recorded 5 months after the stroke. However, the differences could also result from the diverse locations of the lesions. Although the exact topography of the PN is unknown in humans, it is possible to distinguish the two groups of PN in which we are interested—that is, the LPN-DLPN

group and the DMPN group. According to Schmahmann and Pandya,⁶ these two groups are separated by another PN group, the peduncular PN, intermingled with the corticospinal tract. Therefore, the DLPN-LPN group and the DMPN group lie respectively laterally and medially to a virtual anteroposterior line crossing the pons through the central part of the peduncular PN (see fig 2). Thus, it is reasonable to assume that lesions located laterally or medially to this line involve either the DLPN-LPN group or the DMPN group, respectively. According to these anatomical criteria, the DLPN and the LPN were probably extensively damaged in patient 1 (given the large rostrocaudal extent of this lesion), slightly damaged in patient 2, and intact in patients 3 and 4.

Conversely, the DMPN were partly damaged unilaterally in patients 3 and 4, and bilaterally in patient 2, but spared in patient 1. From a comparison of patient 1 and patient 2, it may be suggested that the extensive impairment of the DLPN and the LPN was responsible for the severe impairment of ipsilateral smooth pursuit in patient 1. Moreover, a comparison of patients 3 and 4 with patient 2 suggests that the more pronounced impairment of ipsilateral smooth pursuit in patient 2 could be the consequence of the involvement of the DLPN in this patient, the DMPN being partly damaged in all these three patients. Lastly, impairment of horizontal OKN and vertical smooth pursuit in particular in patients 1 and 2, were consistent with results of experimental DLPN lesions.²⁵

Smooth pursuit impairment was less asymmetrical in patient 2 than in patient 1, partly because of a relatively more marked contralateral smooth pursuit deficit in the former, especially for high target velocities (29 and 45°/s). Patients 3 and 4, with DMPN lesions, had, respectively, slight and no asymmetry in smooth pursuit (fig 7). Slight asymmetry after a DMPN lesion may be due to the medial location of these nuclei. Since the two groups are located on either side of the midline, and their efferences decussate through the basis pontis before projecting to the cerebellum, a single medial lesion may affect both nuclei (as in patient 2) and their efferences. It should also be noted that these nuclei receive bilateral afferences from the FEF. The severe impairment of contralateral smooth pursuit in patients 1 and 2 appears to contradict experimental studies in the monkey, in which DLPN lesions result in only slight or no impairment of contralateral smooth pursuit.²⁵ However, these chemically induced lesions, performed by excitotoxic agents, such as ibotenic acid, selectively damage cell soma but spare fibres of passage—that is, efferences from the contralateral pontine nuclei. Therefore, this could explain the difference between the results of experimental and clinical studies.

Our findings in patient 1 are consistent with the results of Thier *et al.*⁴ These authors reported the first case of selective smooth

Figure 7 Index of asymmetry of smooth pursuit. Values for each control group are plotted as horizontal bars displaying mean index of asymmetry $\pm$ SD. Note that patient 1, with a DLPN and LPN lesion, had the most marked asymmetry, whereas patients 3 and 4, with DMPN lesions, had slight and no asymmetry, respectively.

pursuit impairment after a PN lesion. According to MRI, the lesion probably involved the LPN-DLPN group. Saccades were normal but smooth pursuit was markedly impaired, bilaterally although mostly ipsilaterally, resulting in a high level of asymmetry. To our knowledge, no previous smooth pursuit study has been reported in a patient with a medially located pontine lesion, considered to involve the DMPN.

Therefore, our results appear to confirm the involvement of the DLPN and LPN in smooth pursuit control, and suggest that the DMPN could be involved in this eye movement as well, though with a minor role. As for the NRTP, its role in smooth pursuit in humans remains to be determined, since this structure was probably spared, either totally or largely, in our four patients.

VESTIBULO-OCULAR REFLEX

Since the VOR of patient 1 was not tested in complete darkness and was analysed only qualitatively, a slight abnormality of this eye movement cannot be ruled out. VOR suppression was impaired bilaterally in this patient but, unlike smooth pursuit, was symmetrical. A similar discrepancy between smooth pursuit and VOR suppression results was also observed in the patient previously reported.⁴ It has been suggested that VOR suppression does not result only from additional mechanisms between the VOR and smooth pursuit.

In patient 2, rightward gain was about 2.20, whereas leftward VOR gain was normal. Increased VOR gain is uncommon. In humans, bilateral hyperactive VOR has been

observed in cerebellar degeneration,³²⁻³⁴ and in the monkey, hyperactive VOR has been produced by a reversible lesion affecting the olivofloccular tracts or the inferior olivary nucleus.³⁵ The lesion of patient 2 did not appear to involve the flocculus, the olivary nucleus, or the flocculovestibular and olivocerebellar tracts, both passing through the inferior cerebellar peduncle. Therefore, the explanation for such a unilateral hyperactive VOR is unclear. It may be that damage to the afferences of the inferior olivary nucleus was responsible for this abnormality. VOR suppression was likewise impaired bilaterally in patient 2, but predominantly for the rightward hyperactive VOR. However, as the index of asymmetry of the VOR under the second condition and VOR suppression were analogous, it may be suggested that asymmetry observed in VOR suppression was mainly the consequence of VOR asymmetry. In patients 3 and 4, the VOR tested under both conditions was normal. VOR suppression was mildly impaired bilaterally, without asymmetry.

SACCADES

Patient 2 had reduced velocity of all horizontal saccades. As no lesions were visible on MRI in the cerebral hemispheres or in the midbrain, it may be suggested that this abnormality was due to the pontine lesion. In the monkey,²⁵ as well as in the previously reported case⁴ or in our patient 1, DLPN or LPN lesions did not result in a decrease in saccade velocity. Moreover, a lesion in the DMPN area does not seem to reduce saccade velocity, as shown by patients 3 and 4.

Therefore, it may be assumed that this saccade abnormality was due to the small median tegmental extent of the lesion, probably involving the pontine paramedian reticular formation (PPRF). The lesion of patient 4 impinged also slightly in the pontine tegmentum, but to a lesser extent than that of patient 2. Therefore, the PPRF was probably spared in this patient, with saccades of normal velocity.
