LESSON OF THE MONTH

A case report of paroxysmal dystonic choreoathetosis due to hypoglycaemia induced by an insulinoma

Christopher Shaw, Lindsay Haas, David Miller, John Delahunt

Abstract

Hypoglycaemia due to an insulinoma can mimic acute disorders of cognition, consciousness, epilepsy, transient ischaemia, or psychosis, and chronic disorders of dementia and neuropathy. Misdiagnosis and delay in treatment are common and prolonged hypoglycaemia can lead to permanent neurological deficit or fatal coma. A 27 year old woman with hypoglycaemia induced by an insulinoma presented with features typical of paroxysmal non-kinesiogenic dystonic choreoathetosis. Striatal dysfunction as a consequence of hypoglycaemia has rarely been described. Insulinoma is a readily treatable condition that should be considered in the differential diagnosis of a paroxysmal movement disorder.

(*J Neurol Neurosurg Psychiatry* 1996;61:194-195)

Keywords: paroxysmal dystonic choreoathetosis; hypoglycaemia; insulinoma

Paroxysmal non-kinesiogenic dystonic choreoathetosis (PDC) describes attacks of dystonic posture, chorea, athetosis, or ballism in any combination. Typically the episodes last between five minutes and four hours, being longer in duration but less frequent than paroxysmal kinesiogenic choreoathetosis (PKC). They are not precipitated by sudden movement or startle and do not respond to anticonvulsants. Speech may be affected by dystonia and patients often report abnormal sensations in their limbs at the start of an attack. Most reported cases of PDC are idiopathic or familial in aetiology and when associated with exercise are considered to be an intermediate form of PDC.¹ Our patient presented with features of exercise associated PDC due to hypoglycaemia caused by an insulinoma.

Case report

A 27 year old woman developed episodes of exercise associated postural disturbance and involuntary movement over a period of four months. The first episode occurred after a morning aerobics session, when she found her-

self bumping into people and involuntarily backing away when she wanted to stand still and talk. A fortnight later when she was walking home from work she felt that her right shoe did not fit properly and that she did not know where it was when she put it down. On arriving home she noticed a brief episode of horizontal diplopia and poor balance with difficulty maintaining her posture while putting her right leg into her trousers. This episode lasted 30 minutes and resolved completely after eating food. Another episode occurred while driving when she lost control over the accelerator pedal causing her to accelerate involuntarily. The most dramatic episode occurred while attending a conference. She had omitted breakfast and was taking a walk after a long lecture when she felt tightness in both calves and her shoes felt as if they did not fit properly. Her right foot cramped into a flexed and inverted posture. She sat down in a café and noticed clumsiness in placing her cup in its saucer and her speech became slow. She walked back to the conference but had difficulty controlling her right leg. As she seated herself, her legs felt restless. Witnesses described rocking movements of her trunk with irregular jerking and writhing movements of her limbs and torso with frequent arching of her back. She was assisted from the room and the movements settled slowly, lasting 30 minutes in total. Afterwards she felt nauseated and resisted efforts to take her to hospital in an ambulance. Her serum glucose was recorded at 3.2 mmol/l on arrival and on eating food she completely recovered apart from a diffuse headache. Apart from a grade II systolic murmur her general physical and neurological examinations were normal. Blood tests including random glucose blood film, erythrocyte sedimentation rate, thyroid function, copper, and caeruloplasmin were all normal. Her autoantibody screen detected a weakly positive antinuclear antibody at 1:20 in a speckled diffuse pattern. Her EEG was normal. Head CT disclosed abnormal enhancement at the left cerebellopontine angle but vertebral angiography showed this to be a tortuous basilar artery. The working diagnosis was of vertebrobasilar migraine until she developed a further attack of choreoathetoid movements and dystonic posturing of her limbs and trunk during an afternoon outpatient clinic. Results of prolonged fast demonstrating spontaneous hypoglycaemia

Time (h)	0800	1020	1230	1300	1330	1440
Blood sugar (mmol)	2.4	1.7	1.5	1.6	1.6	2.1
Insulin (pmol)	25	39	42	44	39	48
C peptide (pmol)	246	341	381	430	432	465

After 29 hours blood sugar fell to < 2.5 mmol with high concentrations of insulin (fasting range 5–75 pmol, and in the presence of hypoglycaemia < 5 pmol) and C peptide (fasting range 250–1100 pmol, and in the presence of hypoglycaemia < 200 pM) suggesting inappropriate endogenous insulin secretion.

taken shortly after this had a glucose concentration of 1.7 mmol/l (normal > 2.5 mmol/l) and her symptoms resolved on eating. An insulin challenge test showed inappropriately raised concentrations of C peptide, confirming endogenous insulin secretion. Twenty nine hours of fasting test provoked spontaneous hypoglycaemia with a blood sugar of 1.5 mmol and inappropriately high insulin and C peptide concentrations (table). Proinsulin was 30% of the detectable insulin (normal < 5%), supporting the diagnosis of insulinoma and suggesting a benign tumour (carcinoma often > 60%). Abdominal CT was normal but coeliac axis angiography suggested a small tumour in the tail of the pancreas. At operation a 2 cm tumour was resected and histology showed nests of islet cells. Immunohistochemical staining and electron microscopy confirmed the presence of insulin. Postoperatively the patient reported a significant improvement in her intellectual performance and there was no recurrence of her symptoms during a five year follow up.

Discussion

Paroxysmal movement disorders have been symptomatic of hypoglycaemia in only two contemporary case reports. Newman and Kinkel reported a diabetic woman who developed two episodes of limb choreoathetosis and opisthotonus associated with hypoglycaemia after a morphine injection for severe headache and vomiting.² Winer *et al* described a woman with an insulinoma who, when recovering from hypoglycaemic attacks, adopted tonic flexion of her arms, extension of her legs and laterocollis, and flexion of the trunk.³ Historical reports of insulin shock therapy describe transient choreoathetosis in some patients⁴ but more commonly the disorder was permanent.⁵

Many patients with an insulinoma do not report the adrenergic symptoms of hypoglycaemia and present with neurological or psychiatric manifestations that often lead to misdiagnosis.^{6–7} In Daggett and Nabarro's review of 252 reported cases the most common neurological symptoms were confusion, coma, and seizures. Non-specific headache, generalised weakness, paraesthesia, and stroke-like paralysis were less frequent and

dizziness and dysarthria were uncommon.⁸ Chronic neuropathic and dementing syndromes due to hypoglycaemia have also been described.^{9,10} In a prospective survey, two of 25 patients referred to neurologists with "funny turns" were found to have an insulinoma.¹¹

Huntingdon's disease is associated with striatal degeneration and hypometabolism on ¹⁸F-fluorodeoxyglucose and PET imaging,¹² whereas the reversible choreas such as Sydenham's chorea, systemic lupus erythematosus, and antiphospholipid syndrome show striatal hypermetabolism.^{13–15} The precise pathophysiology of chorea in these conditions has not been established but we postulate that in our patient hypoglycaemia led to temporary striatal dysfunction. This in turn may have led to defective pallidal and subthalamic inhibitory outflow to the thalamus, with overactivity of thalamocortical excitatory projections resulting in hyperkinesia. In the absence of a recognised predisposing factor for chorea we postulate that the striatal response to hypoglycaemia must vary between subjects.

Hypoglycaemia due to insulinoma is uncommon and difficult to diagnose as it mimics a great variety of neurological conditions. It may have grave consequences but is often curable and must be considered in the differential diagnosis of a paroxysmal movement disorder.
