Interferon- γ induced increases in intracellular calcium in T lymphocytes from patients with multiple sclerosis precede clinical exacerbations and detection of active lesions on MRI

G Martino, M Filippi, V Martinelli, E Brambilla, C Gobbi, G Comi, L M E Grimaldi

Abstract

Background—Interferon (IFN)- γ exerts a multiplicity of actions potentially relevant for the pathogenesis of multiple sclerosis, including the expression of a transplasma-lemma calcium (Ca^{2+}) influx leading to an intracellular Ca^{2+} ($[\text{Ca}^{2+}]_i$) increase able to lower T lymphocyte threshold of excitability. It has been previously shown in a cross sectional cumulative study that this influx is associated with clinical and MRI evidence of disease activity.

Methods—To evaluate the temporal relation between disease activity and the IFN- γ activated Ca^{2+} influx in individual patients, a fluorimetric analysis was performed on peripheral blood lymphocytes from eight patients with relapsing-remitting multiple sclerosis every 15 days for one year. **Results**—Fluctuations of the influx were correlated with clinical events and monthly enhanced brain MRI. The influx was detected a mean of 10.4 (range 7-17) times per patient during our analysis. In 61% of the occasions, influx induced $[\text{Ca}^{2+}]_i$ increases were recorded in each patient in more than two consecutive measurements, determining sustained $[\text{Ca}^{2+}]_i$ increases lasting for a mean of 31.5 days. Peak $[\text{Ca}^{2+}]_i$ increases preceded clinical attacks ($P=0.04$) or maximal detection of brain MRI enhancing lesions ($P=0.05$) by a mean of 30.8 and 34.2 days respectively. Spectral analysis of time series further indicated that the fluctuation frequency of $[\text{Ca}^{2+}]_i$ increases due to the influx over time were superimposable on the appearance of new MRI lesions in all patients and confirmed that in two thirds of the patients these $[\text{Ca}^{2+}]_i$ increases occurred significantly before ($P<0.005$) or concurred with new lesion appearance. Finally, the overall presence of the influx throughout the follow up period correlated ($P=0.03$) with the patients' exacerbation rates.

Conclusions—Intracellular events leading to T lymphocyte activation in multiple sclerosis occur in the peripheral blood before CNS specific events become evident and are, in part, sustained by cytokine induced Ca^{2+} mediated phenomena.

Keywords: multiple sclerosis; interferon- γ ; lymphocytes; calcium; MRI

A major part in the pathogenic mechanisms leading to CNS demyelination in multiple sclerosis is played by activated T lymphocytes.¹ Their activity is regulated by a complex network of cytokines among which interferon (IFN)- γ is considered essential.²

We have recently shown that T lymphocyte activation in multiple sclerosis is partially dependent on a novel transmembrane IFN- γ activated calcium (Ca^{2+}) influx which is mainly expressed on CD4^+ cells.³⁻⁴ The influx is associated with phases of disease activity⁵ and facilitates T cell proliferation in response to activator stimuli.⁶

To evaluate the temporal relation between this Ca^{2+} influx and clinical and MRI evidence of disease activity in multiple sclerosis, we correlated the presence of the influx with clinical exacerbations and gadolinium enhancing brain MRI lesions in eight patients with relapsing-remitting multiple sclerosis followed up every two weeks for one year.

Materials and methods

PATIENT SELECTION

Peripheral blood lymphocytes were obtained every 15 days for one year from eight patients (six women, two men; mean age 25, range 21-37 years) affected by clinically definite multiple sclerosis (mean disease duration 6.3, range 2-10 years) according to the criteria of Poser *et al.*⁷ The clinical course of the disease was relapsing-remitting in all patients. Patients were clinically evaluated using the expanded disability status scale (EDSS; mean score at entry 2.5).⁸ Patients were considered to be in an active phase of the disease when experiencing an episode of symptoms, documented on examination, indicative of a neurological abnormality attributable to acute demyelination in one or more regions of the CNS; the symptoms had to last more than 24 hours and be separated from a previous attack by at least one month. Patients experiencing a new attack of the disease were always treated with a two to three week course of steroids.

DETECTION OF THE IFN- γ ACTIVATED Ca^{2+} INFLUX BY FLUORIMETRIC ANALYSIS

To evaluate the presence of the IFN- γ activated Ca^{2+} influx, macrophage depleted human peripheral blood lymphocytes were analysed by fluorimetry every 15 days as recommended by Gryniewicz *et al.*⁹ but modified according to the Ca^{2+} free Ca^{2+} reintroduction protocol.¹⁰ This protocol allows the characterisation of the increases of intracellular Ca^{2+} ($[\text{Ca}^{2+}]_i$) concentrations, measured by conventional fluorimetry, as due to Ca^{2+} release from intracellular stores or to Ca^{2+} influxes from outside the cell. Briefly, cell samples were supplemented with excess ethylene glycol-bis (β -aminoethyl ether) N,N,N',N'-tetra-acetic acid (EGTA; 3 mM) to chelate extracellular Ca^{2+} before fluorimetric analysis. After one minute 1 pg/ml IFN- γ (specific activity 1×10^7 U/mg; Genzyme, Cambridge, MA, USA), which was found to be the optimal dose to stimulate the IFN- γ activated Ca^{2+} influx in peripheral blood lymphocytes in preliminary dose-response experiments,^{5,6} was added. Then Ca^{2+} (3 mM) was reintroduced into the medium after four additional minutes and the ensuing $[\text{Ca}^{2+}]_i$ peak, indicating Ca^{2+} influx from outside the cell due to the IFN- γ activated influx, was then measured.

The increase in $[\text{Ca}^{2+}]_i$ in response to IFN- γ occurring in peripheral blood lymphocytes from patients with multiple sclerosis was expressed as the percentage of $[\text{Ca}^{2+}]_i$ increase over basal level. To calculate the percentage increase of $[\text{Ca}^{2+}]_i$ over basal concentration due to the IFN- γ activated Ca^{2+} influx we previously subtracted from the IFN- γ induced $[\text{Ca}^{2+}]_i$ increase the percentage of $[\text{Ca}^{2+}]_i$ increase due to the small cytosolic $[\text{Ca}^{2+}]_i$ changes occurring in non-stimulated cells as a consequence of medium Ca^{2+} chelation and reintroduction.¹⁰ However, due to the high frequency of spontaneous $[\text{Ca}^{2+}]_i$ oscillations occurring in non-stimulated lymphocytes¹¹ and to the necessity of standardising our assay to perform longitudinal studies on large cohorts of patients, we introduced more stringent criteria. We now perform three fluorimetric analyses per patient on different cell preparations obtained from the same blood sample. Each analysis consists of two recordings of variations in $[\text{Ca}^{2+}]_i$ (performed in parallel on two different aliquots of the same cell preparation): the first one in the absence of any stimulus, and the second one in the presence of 1 pg/ml IFN- γ . At the end of both recordings, the $\%[\text{Ca}^{2+}]_i$ increase after Ca^{2+} reintroduction in the absence of any stimulus (already subtracted by the small cytosolic $[\text{Ca}^{2+}]_i$ changes occurring as a consequence of the protocol used; see above) is subtracted from the $[\text{Ca}^{2+}]_i$ increase recorded in response to IFN- γ . A patient is considered influx positive only when the difference of $[\text{Ca}^{2+}]_i$ increase is higher than 1% in at least two of three experiments. The final value is the mean of the values calculated in the three fluorimetric analyses. With these criteria we recorded an intra-assay variability <20% (a 1% $[\text{Ca}^{2+}]_i$ increase over basal concentration due to the IFN- γ influx corresponds to 1% (SD 0.05)).

MRI STUDIES

Brain MRI was performed monthly in all patients with a 1.5 Tesla machine (Siemens SP63, Erlangen, Germany). Five mm contiguous axial T1 weighted (SE 600/17; field of view=230 mm, matrix size=198x256; two excitations) slices throughout the whole brain were obtained five to seven minutes after the injection of gadolinium-diethylenetriamine penta-acetic acid (0.1 mmol/kg intravenously over one to two minutes). New or persisting enhancing lesions were counted in each scan by one of us (MF), unaware of the clinical status and fluorimetric results. An arbitrary scoring system was used to estimate the size of the lesions: 1 point was given for each lesion with a diameter 1–5 mm, 2 points for 6–10 mm, and 3 points for lesions >10 mm in size. The total score represented the lesional burden of each patient.

MEASUREMENTS OF TUMOUR NECROSIS FACTOR- α (TNF α) mRNA

Total RNA was isolated from peripheral blood lymphocytes using guanidine-isothiocyanate solution and purified by ultracentrifugation on a caesium chloride gradient. A T primed first strand kit was used for the reverse transcription of total RNA into cDNA (Ready-to-go kit, Pharmacia, Upsala, Sweden). Polymerase chain reaction amplification of cDNA sequence specific for TNF α was performed using 1 μM cytokine primers, 200 μM of each dNTP, 50 mM KCl, 10 mM Tris HCl (pH 8.3), and 1.5 mM MgCl_2 . After a hot start at 95°C for five minutes, 1 U Taq polymerase was added and 25 polymerase chain reaction cycles were carried out. Each cycle consisted of one minute of amplification at 95°C, one minute of primer annealing at 60°C, and one minute of product dissociation at 72°C. The number of amplification cycles was selected based on preliminary experiments on cDNA from the U937 cell line. The number of cycles was varied from 10 to 40, in 5 cycle increments, and we found that 25 cycles were in the exponential part of the amplification curve. Amplified polymerase chain reaction products were visualised in ethidium bromide stained 1% agarose gels run in TAE buffer, blotted on to nylon membranes, and hybridised with specific ³²P labelled probes (Ready Prime kit, Amersham, Buckinghamshire, UK) representing the amplified region. Probes were obtained by elution of RT-polymerase chain reaction products from the U937 cell line representing a specific sequence of TNF α . Autoradiograms of the probed TNF α polymerase chain reaction products were quantified by densitometry (Computing Densitometer, Molecular Dynamics; Image Quant Software, version 3.3). The raw data was normalised against the intensity of the β actin band. For comparisons between subject, the normalised intensities were further corrected using the normalised intensities of the U937 cell derived positive controls. All cDNA samples from each patient were run in the same polymerase chain reaction round. To minimise experimental errors, all cDNA samples from a given patient were amplified simultaneously

and a positive control, U937 cell cDNA, was included in every polymerase chain reaction experiment.

The following primers were used: TNF α (product: 490 bp), antisense 5'-GAC CTC TCT CTA ATC AGC CC-3', sense 5'-CAG ACC CGT CCA GAT GAA AC-3', β -actin (product: 658 bp); antisense 5'-CTA GAA GCA TTT GCG GTG GAC GAT G-3', sense 5'-ACG GGG TCA CCC ACA CTG TGC-3'.

STATISTICAL ANALYSIS

As the presence of the IFN- γ activated Ca²⁺ influx as well as number of gadolinium enhancing MRI lesions tended to vary during the study, we plotted all [Ca²⁺]_i increases due to the influx and variations in MRI lesion number over time and obtained a temporal distribution of the two variables for each patient. IFN- γ induced maximal [Ca²⁺]_i increases over basal concentrations and maximal number of MRI enhancing lesions were considered as peaks. The Mann-Whitney *U* test was applied to correlate peaks, MRI lesions, and clinical attacks.

We also evaluated whether the clinical activity of the disease was influenced by the presence of the influx by regression analysis: the area under the curves generated by the [Ca²⁺]_i fluctuations due to the influx (indicating how many influx positive cells for how long) was compared with the number of each patient's exacerbations during the follow up period. Area under the curves was calculated with the following formula:

$$\text{area} = \sum \frac{(T_n - T_{n-1}) (Y_n - Y_{n-1})}{2}$$

where *T* represents time of influx detection and *Y* the percentage increase of [Ca²⁺]_i over basal concentration due to the influx. Regression analysis was also used to compare (1) the total number of enhancing lesions detected by MRI in each scan with the total lesion score and the total number of new enhancing lesions, and (2) the temporal relation between TNF α mRNA concentrations and the [Ca²⁺]_i increase due to the IFN- γ activated influx.

To further evaluate the relation between variations of IFN- γ induced [Ca²⁺]_i and number of brain MRI enhancing lesions, we performed a spectral analysis which considers the two variables as time series. The relation between variations in [Ca²⁺]_i and clinical attacks were not analysed by spectral analysis due to the temporal characteristics of clinical attacks, which were not suitable for time series analysis. According to time series analysis,¹² we first estimated the spectrum and the cross spectrum of the two variables in each patient with multiple sclerosis. Spectra represent the decomposition of the variance of the time series into their cyclical components (frequency). Then, to investigate the delay between the two time series, we focused on a specific function derived from the cross spectrum and named the phase spectrum. The delay was estimated by the slope of the regression line between the phase spectra and the frequency.

The different sampling grid for the two time series plus the irregularity of the sampling scheme led to some missing values. We completed the time series by linear interpolation and the analyses were performed on these modified time series.

Results

FLUORIMETRIC ANALYSIS

Eighty five of the 183 (46%) fluorimetric evaluations in T lymphocytes from the eight patients with relapsing-remitting multiple sclerosis showed the presence of the IFN- γ activated Ca²⁺ influx. Influx positive lymphocytes were found a mean of 10.4 times (95% confidence interval (95% CI) 7.9 - 12.8) per patient. The influx determined a mean of maximal [Ca²⁺]_i increases of 23.7 (95% CI 17.7 - 29.7)% over basal concentrations.

In 61% of occasions the influx was detected for more than two consecutive fortnightly measurements. Consecutive detections were interpreted as persistence of the influx determining a sustained [Ca²⁺]_i increase. These increases lasted for a mean of 31.5 (95% CI 23.3 - 39.5) days.

The influx had already disappeared at the beginning of the steroid treatment for eight clinical attacks. In two attacks the influx continued to increase during steroid administration. In the remaining seven attacks, the influx was already decreasing at the beginning of steroid treatment (fig 1 A).

RELEVANCE OF IFN- γ INDUCED [Ca²⁺]_i VARIATIONS TO CLINICAL ATTACKS

The persistence of the influx and its tendency to fluctuate determined different curves of [Ca²⁺]_i in each patient which were plotted over time. Maximal [Ca²⁺]_i increases within sustained curves (mean 4.5 peaks per patient, range 3-6; fig 1A) were considered for statistical analysis as markers of maximal T lymphocyte activation and were compared with clinical attack occurrence.

The eight patients with relapsing-remitting multiple sclerosis studied experienced 17 clinical attacks during the study (one patient four attacks; two patients three attacks; three patients two attacks; one patient one attack; one patient no attacks) (mean annual exacerbation rate 2.1). The influx was detectable at the beginning of 10 (59%) clinical attacks but had already subsided by the beginning of the remaining seven attacks. [Ca²⁺]_i peaks never coincided with the beginning of a clinical attack but were found within 45 days before the onset of clinical symptoms in 15 of the 17 (88%) clinical attacks. The increased frequency of the [Ca²⁺]_i peaks (mean 4.5 peaks/year/patient) made it difficult to interpret the temporal relation between T lymphocyte specific events and clinical attacks. However, as the time elapsed between a [Ca²⁺]_i peak and the next clinical attack was significantly shorter (*P*=0.05) (mean 30.8; 95% CI 11.6 - 49.9) days than that between a clinical attack and the ensuing [Ca²⁺]_i peak (mean 50.5; 95% CI 30.2 - 70.5 days) (fig 2 A), we favour a non-random

Figure 1 Time course of (A) IFN- γ activated Ca^{2+} influx, (B) TNF α mRNA concentrations, and (C) number of brain MRI enhancing lesions in one representative patient with relapsing-remitting multiple sclerosis. The influx is expressed as % of $[\text{Ca}^{2+}]_i$ increases over basal values in response to IFN- γ stimulation, TNF α mRNA is expressed as arbitrary units (ratio between densitometric values of TNF α and β -actin mRNA concentrations) and MRI lesions are represented by the number of gadolinium enhancing lesions disclosed by brain MRI. The black box at the bottom of the lower panel represents days of steroid treatment. The arrow and the dashed line indicate onset of clinical attacks. NA=not available.

association between $[\text{Ca}^{2+}]_i$ peaks and clinical exacerbations.

The area under the curves generated by the $[\text{Ca}^{2+}]_i$ fluctuations due to the influx significantly correlated ($r=0.72$; $P=0.03$) with the patients' exacerbation rates during the follow up period further suggesting that the clinical activity of the disease was influenced by the presence of the influx.

BRAIN MRI LESIONS AND IFN- γ INDUCED $[\text{Ca}^{2+}]_i$ VARIATIONS

During the study we performed 80 gadolinium enhanced brain MRI scans. Four patients had 12 monthly scans, two patients had 11 monthly scans, and two patients had five monthly scans. A total of 462 enhancing lesions were found in 66 scans (343 lesions were new and 119 were

persisting from at least the previous scan); no enhancing lesions were detected in the remaining scans. Lesion scores varied between patients from 0 to 51 (mean 7.3 (SD 9.2)).

We first plotted the total number of active lesions per scan over time and generated for each patient curves reflecting disease activity as detected by MRI (fig 1 C). As the total score as well as the number of new enhancing lesions for each scan generated curves which were superimposable to those generated using the total number of enhancing lesions in all patients (total number of lesions v score: $r=0.98$, $P<0.001$; total number of lesions v new lesions: $r=0.93$, $P<0.001$), we adopted the maximal number of enhancing lesions (MRI peaks) as a marker of CNS inflammation. A total of 20 MRI peaks were recorded (mean

Figure 2 Mean number of days elapsed between maximal IFN- γ induced $[Ca^{2+}]_i$ increases (referred to as peaks in the text) and clinical attacks (panel A) or maximal number of gadolinium enhancing brain MRI lesions (panel B) (before = black bars; after = grey bars). Lines at the top of each bar represent 95% CI. P values were obtained by Mann-Whitney U test.

MRI peaks per patient 2.5, range 1-4). An MRI peak was observed at the time of nine of 15 (60%) clinical attacks; in the remaining two attacks MRI was not performed. We then analysed the temporal relation between MRI peaks and $[Ca^{2+}]_i$ peaks due to the influx. As with clinical attacks, the time elapsed was significantly shorter between an MRI peak and the preceding $[Ca^{2+}]_i$ peak (mean 34.2; 95% CI 17.5 - 51.1 days) than between an MRI peak and the following $[Ca^{2+}]_i$ peak (mean 54.3; 95% CI 35.1 - 73.6 days) ($P=0.05$), again suggesting a non-random occurrence of the two events (fig 2 B).

To further analyse the relation between fluctuation of the number of brain MRI gadolinium enhancing lesions and IFN- γ induced $[Ca^{2+}]_i$ variations we transformed these two variables in time series and compared them by spectral analysis. The estimated spectra of the two time series were concordant in each of the seven patients analysed (fig 3, left sided panels). One patient was not analysed because the available observations were not sufficient to generate reliable time series. Because we found that MRI and Ca^{2+} variations showed superimposable spectra over time, we calculated the delay between the two time series. We found that the $[Ca^{2+}]_i$ increase due to the IFN- γ influx preceded appearance of brain MRI gadolinium enhancing lesions in three of seven (43%) patients by a mean of 26 (SD 8.1) days (fig 3 A, B, and C); the two events concurred in two patients (28%) (fig 3 D and E) whereas in the two (28%) remaining patients the Ca^{2+} influx followed MRI lesion appearance by a mean of 25 (SD 0.025) days (fig 3 F and G). These results indicated that in at least two thirds of our patients the maximal activity of the influx occurred before or concomitantly with the appearance of inflammatory lesions within the CNS, further supporting the non-random occurrence of the activity of the IFN- γ activated Ca^{2+} influx with reference to phases of multiple sclerosis disease activity.

CORRELATION BETWEEN TNF α MRNA CONCENTRATIONS AND IFN- γ -ACTIVATED $[Ca^{2+}]_i$ INFLUX

TNF α mRNA concentrations and the IFN- γ activated Ca^{2+} influx were measured in two aliquots of the same peripheral blood lymphocyte samples in one of the eight patients with relapsing-remitting multiple sclerosis every 15 days for 10 months (294 days). Concentrations of TNF α mRNA ranged between 0 and 1.9 (mean 0.22 (SD 0.49)) arbitrary units whereas the IFN- γ activated Ca^{2+} influx ranged between 0 and 13 % (mean 3.7 (SD 5.0) %).

When we generated two curves representing over time the two variables, three TNF α mRNA peaks and two IFN- γ induced $[Ca^{2+}]_i$ peaks became visible. The two TNF α peaks were temporally superimposable with those determined by the IFN- γ activated Ca^{2+} influx (fig 1 B). Regression analysis comparing values of the two variables confirmed the temporal association of the two events ($r=0.57$; $P=0.02$).

Discussion

Part of the contribution of IFN- γ to T lymphocyte activation in multiple sclerosis is exerted via a transmembrane IFN- γ activated Ca^{2+} influx^{3,4} which facilitates T cell proliferation in response to activating stimuli.⁶ In a recent cross sectional study, including 67 patients with relapsing-remitting multiple sclerosis, we found that the presence of the influx correlated with MRI or clinical evidence of inflammation of the CNS.⁵ However, its absence in almost 30% of patients with multiple sclerosis experiencing a phase of disease activity questioned the specificity of the event.

We now report on the temporal relation between the detection of the influx and clinical or MRI evidence of disease activity in eight patients with relapsing-remitting multiple sclerosis followed up every 15 days for one year. We found that the IFN- γ activated Ca^{2+} influx fluctuates over time in peripheral blood lymphocytes from patients with multiple sclerosis, becoming undetectable within 30 days of its appearance. As we noted in previous studies, the influx is not detectable in 40% of cases by the time of the clinical attack, having probably exhausted its contribution to the pathogenesis of multiple sclerosis in earlier stages (during T lymphocyte activation). However, we found that the fluctuations of the influx significantly heralds clinical attacks and the detection of enhancing lesions. The peak activity of the influx as well as its highest frequency (reflecting T cell activation in the peripheral circulation) falls about 25-30 days before clinical attacks and maximal MRI evidence of CNS inflammation and fosters almost 90% of all clinical attacks. The clinical relevance of the influx is also supported by the significant correlation between the detection of IFN- γ activated Ca^{2+} influx positive T lymphocytes over time and the annual exacerbation rates of patients with multiple sclerosis.

Why does it take four to five weeks for peripherally activated CNS specific clones to leave their peripheral location and reach the CNS? Although full blown immune responses require only a few days or weeks to take place, studies employing the chronic experimental allergic encephalomyelitis model in rodents and non-human primates have shown that widely ranging periods of time (from one week to six months) can separate immunisation from

Figure 3 Left side panels represent spectra of the two time series (dashed line=numbers of gadolinium enhancing brain MRI lesions; continuous line=IFN- γ activated Ca^{2+} influx measured as % $[\text{Ca}^{2+}]$, lymphocytic increase after IFN- γ stimulation) in each of the seven patients with multiple sclerosis studied (patients A-G). The spectra of the two variables are concordant in each patient. Right side panels show phase spectrum v frequencies. Regressions between the two variables are indicated. Negative slopes indicate that the $[\text{Ca}^{2+}]$ increase series precedes the brain MRI gadolinium enhancing lesion series. Each row (left and right sided panels) describes results in one of the patients with multiple sclerosis.

appearance of active disease or two consecutive spontaneously occurring attacks.^{13–15} This finding can be in part explained by genetic predisposition (for example, HLA background) as well as environmental triggering factors (for example, viral infections). Our finding of a lag time of 10 to 50 days occurring between peak activity of the IFN- γ activated Ca^{2+} influx and MRI or clinical signs of disease activity in patients with multiple sclerosis is in line with experimental evidence. These findings, along with results of our spectral analysis, explain the apparent paradox we previously reported of a T cell phenomenon relevant for immune activation in multiple sclerosis⁶ but not detected in 20 to 30% of patients with multiple sclerosis at the time of clinical or MRI active phases of the disease.^{3–5} The activity of the influx actually signals one of the earliest immunological events leading to demyelination in patients with multiple sclerosis, as suggested by spectral analysis, which showed that the IFN- γ influx activity (frequency) precedes or concurs with phases of disease activity (MRI active lesions) in almost two thirds of the patients.

In a preliminary study involving four patients with relapsing-remitting multiple sclerosis tested at the beginning and at the end of a clinical attack, we reported that steroid treatment seemed to foster the disappearance of the influx.⁵ From the present more thorough longitudinal study, it seems that the response to steroids is not stereotyped. The influx either disappeared before, appeared after, or was active during the steroid treatment. Although this variability questions a specific role of steroids in influencing the influx kinetics and overall disease activity in multiple sclerosis, we cannot at present exclude that part of the delay from the beginning of the clinical attack to the appearance of the next $[\text{Ca}^{2+}]_i$ peak is due to the steroid treatment.

Increases in TNF α concentration have been recently shown to precede periods of disease activity in multiple sclerosis about one month before clinical exacerbations.¹⁶ We found in one patient with multiple sclerosis that a similar temporal distribution occurs between fluctuations of $[\text{Ca}^{2+}]_i$ due to the IFN- γ activated influx and variations of TNF α mRNA concentrations. Although preliminary, this finding, along with our recent finding of a synergetic effect of TNF α /interleukin (IL)-6/IL-2 with the IFN- γ activated influx in promoting non-antigen specific T cell activation in multiple sclerosis via two different but cooperating intracellular Ca^{2+} -mediated pathways, (Martino *et al*, unpublished data) further supports the proposed synergistic effect between proinflammatory cytokines, such as TNF α and IFN- γ , in orchestrating immune mediated processes relevant for the pathogenesis of multiple sclerosis.¹⁷

In conclusion, we found that the IFN- γ activated Ca^{2+} influx is a dynamic feature of T lymphocytes from patients with relapsing-remitting multiple sclerosis and usually operates before or during clinical or MRI evidence of disease activity. Moreover, as its early detection is associated with preclinical phases of disease activity, it might represent an immunological surrogate marker of disease activity in patients with multiple sclerosis.

This work was supported by grants from Associazione Italiana Sclerosi Multipla (AISM), and the Italian National Research Council. We are indebted to Bruno Colombo, Mariaemma Rodegher, Silvia Mammi, Antonella Poggi, Marco Rovaris, and the staff of the San Raffaele Multiple Sclerosis Center, Department of Neurology, University of Milano for providing patients and contributing to this investigation. We thank Giuseppe Scotti, Adriana Campi, and Clodoaldo Pereira, Department of Neuroradiology, University of Milano, for helping with MRI data collection. We thank Antonella Consiglio for performing TNF α mRNA measurements and Cinzia Ferri for performing part of the fluorimetric analyses.
