PAPER

Prospective validation of a proposal for diagnosis and management of patients attending the emergency department for mild head injury

J Neurol Neurosurg Psychiatry 2004;**75**:410–416

Background: In mild head injury, predictors to select patients for computed tomography (CT) and/or to plan proper management are needed. The strength of evidence of published recommendations is insufficient for current use. We assessed the diagnostic accuracy and the clinical validity of the proposal of the Neurotraumatology Committee of the World Federation of Neurosurgical Societies on mild head injury from an emergency department perspective.

Methods: In a three year period, 5578 adolescent and adult subjects were prospectively recruited and managed according to the proposed protocol. Outcome measures were: (a) any post-traumatic lesion; (b) need for neurosurgical intervention; (c) unfavourable outcome (death, permanent vegetative state or severe disability) after six months. The predictive value of a model based on five variables (Glasgow coma score, clinical findings, risk factors, neurological deficits, and skull fracture) was tested by logistic regression analysis.

Findings: At first CT evaluation 327 patients (5.9%) had intracranial post-traumatic lesions. In 16 cases (0.3%) previously undiagnosed lesions were detected after re-evaluation within seven days. Neurosurgical intervention was needed in 71 patients (1.3%) and an unfavourable outcome occurred in 39 cases (0.7%). The area under the ROC curve of the variables in predicting post-traumatic lesions was 0.906 (0.009) (sensitivity 70.0%, specificity 94.1% at best cut off), neurosurgical intervention was 0.926 (0.016) (sensitivity 81.7%, specificity 94.1%), and unfavourable outcome was 0.953 (0.014) (sensitivity 88.1%, specificity 95.1%).

Interpretation: The variables prove highly accurate in the prediction of clinically meaningful outcomes, when applied to a consecutive set of patients with mild head injury in the clinical setting of a 1st level emergency department.

The assessment of benefits and hazards in the treatment of patients with mild head injury is of paramount importance for public health. Approximately 200–250 cases per 100 000 inhabitants per year are admitted for mild head injury in our region and other European areas.¹ Hundreds of thousands of patients might benefit from simple and widely applicable guidelines to reduce the risk of death or permanent disability by just a few per cent.²

Most patients with mild head injury are currently discharged from the emergency department (ED) without sequelae after a brief observation period. Only a few patients deteriorate within a few days and may require neurosurgical evacuation for an undiagnosed intracranial haematoma.^{3,4} Early computed tomography (CT) has been extensively applied to these patients,⁵ but its systematic use is not recommended, since only 3–13% of patients with a Glasgow coma scale (GCS) score of 15 will have a positive CT scan.⁶ A systematic use of CT involves high costs and legal problems for inappropriate radiological imaging.⁷ The most reliable approach remains the history, physical examination, simple tests, and a selective use of technology to reach maximum accuracy.

Several studies have been published to identify predictors that would clearly indicate which patients should have CT, and/or prolonged observation period for proper discharge planning. The strength of evidence of current recommendations is not enough for routine clinical use.⁶ In a recent survey more than half of emergency physicians claimed that any clinical decision rule for mild head trauma must have a

sensitivity of 100%,⁸ but budget constraints and technology availability must also be considered.

The Neurotraumatology Committee of the World Federation of Neurosurgical Societies (NCWFNS) has recently proposed a new classification and new clinical guidelines. Minor, mild, or trivial head injury are now defined as "mild" head injury, and a proposal for diagnosis, management, and outcome was put forward after literature review and expert consensus.⁹ This proposal allows the diagnostic/therapeutic strategies to be adjusted for locally available resources. In particular, any injury to the head in patients with GCS 14–15 are scored as low risk, medium risk or high risk according to well defined symptoms, signs, and risk factors, and submitted to diagnostic and observation procedures accordingly (table 1).

The proposal is still awaiting proper validation, and also the variables selected for classification require further

evaluation in a real setting. We prospectively assessed the diagnostic accuracy and clinical validity of the variables included in the proposal in a population attending a busy 1st level ED.

PATIENTS AND METHODS

Study population and design

The prospective validation was tested in a three year single centre cohort study, including 6444 consecutive triaged patients, who attended a 1st level ED (51 000 patients per

year, from a population of 171 000 inhabitants) from January 1999 to December 2001. Eligibility criteria were an acute mild head injury, defined by a GCS score of 14 or 15 in patients seen within 24 h from any trauma to the head in local inhabitants aged ≥ 10 years.

The study profile is given in fig 1. Cases who returned for reassessment after discharge (195 cases) were considered only once.

The patients remaining in the study were managed on the basis of the three different risk categories,⁹ with minor

Figure 1 Study profile of patients with different level of risk of complications after mild head injury.

changes (see below). At discharge, all patients received written recommendations for home observation and complaints that would require referral back to hospital for further evaluation. After re-evaluation and negative CT scan, diagnosis of post-concussive syndrome (PCS) was performed in patients who complained of symptoms like headache, dizziness, nausea, weakness, or abnormal drowsiness.¹⁰

Observers were instructed to seek symptoms, signs, and any change in the patient's clinical status for seven days. Final outcome was determined approximately six months after injury. A member of the ED staff contacted all patients with a defined post-traumatic lesion by means of a structured telephone interview. In addition, a systematic search of all patients was carried out by checking the death certificates and the medical databases of our local health district. Patients without post-traumatic lesions who were not readmitted for complaints were considered fully recovered.

The protocol was carried out according to the Helsinki Declaration and approved by the senior staff committee of the Azienda Unità Sanitaria Locale di Forlì.

Patient assessment and management

Patients were classified according to the NCWFNS proposal (table 1⁹), with minor modifications related to CT availability and budget constraints.

After clinical evaluation, low risk patients were sent home without any radiological imaging. Medium risk patients were submitted to a CT scan and discharged after at least 3 h from trauma in the case of negative results. Alternatively they had skull radiography (SR), in which case the observation period was prolonged to 24 h. High risk patients were submitted to CT imaging and managed with a first 24 to 48 h strict observation period,⁹ regardless of CT findings. During the study period, CT was always immediately available during the day, whereas the night service was initially available only on demand. The choice between CT and SR was related to immediate availability of CT, and to the severity of trauma, as judged by the attending physician. To limit the use of CT because of budget constraints, age over 60 years was not considered per se a risk factor.

In our protocol the accepted management options were: (a) monitored in hospital observation; (b) observation in the ED; and (c) home observation under the care of a competent observer, typically a relative or any suitable guardian, after physicians' careful assessment of his/her compliance with instructions.

CT imaging without contrast was performed with a third generation equipment after two or more hours from trauma, with cuts of 10 mm or less from the foramen magnum to the vertex, and including both soft tissue and bone windows. CT scans showing intracranial post-traumatic lesions were real time reviewed by a neurosurgeon of the nearest neurosurgical unit (Cesena, 17 km away), consulted via a teleradiology system.

Measurements of blood alcohol levels, as well as toxicological tests for drugs and/or drugs of misuse, were performed at the discretion of the physician in 703 patients (12.9%) and in 254 cases (4.5%), respectively.

Outcome measures

Three outcomes were considered: any post-traumatic lesion at CT, need for neurosurgical intervention, and unfavourable outcome.

Post-traumatic lesions, requiring admission to hospital and follow up, included: (a) depressed skull fracture (DSF); (b) intracerebral haematoma (ICH)/brain contusion(s); (c) sub-arachnoid haemorrhage (SAH); (d) subdural haematoma (SDH); (e) epidural haematoma (EDH); and (f) intraven-

tricular haemorrhage (IVH).^{11 12} In patients readmitted for complaints a time limit of seven days was set.^{11 12}

Neurosurgical intervention of haematoma evacuation and/or skull fracture elevation was only considered in the first seven days after diagnosis. Late events were not considered in the present analysis.

The final outcome at six months was considered unfavourable if the patient died, remained in a vegetative state, or had a persisting severe disability by the Glasgow outcome scale (GOS).¹³ The follow up GOS was rated by an expert physician unaware of the initial diagnosis, on the basis of the reported response to a structured telephone call.

Analysis

Mean value, standard deviation (SD), median, range, and frequencies were used to describe data distribution. Hierarchical log-linear model and Kruskal-Wallis test were applied in order to compare baseline characteristics among patients. Univariate and multivariate stepwise logistic regression analysis was used to identify factors related to different outcomes. The odds ratio (OR) and 95% confidence intervals (95% CI) were also calculated. A score for risk of post-traumatic lesion was calculated for each patient on the basis of the coefficients computed by the logistic regression derived from variables entering the stepwise procedure. The accuracy of such a risk score was then evaluated by the area under the receiver operating characteristic (ROC) curves.¹⁴ The best cut off was chosen as the value that maximised the likelihood ratio (LR), computed by the following formula: $LR = (\text{probability of true positive} + \text{probability of true negative}) / (\text{probability of false positive} + \text{probability of false negative})$.¹⁵ Sensitivity and specificity were considered at best cut off, as well as, the positive predictive value (PPV) and the negative predictive value (NPV).

Non-parametric estimates of the area under the ROC curves (AUC), together with their respective standard errors, were calculated.¹⁶ Statistical analyses were performed running the SPSS/PC+ statistical package on a personal computer.¹⁷ Two-tailed p values less than 0.05 were considered statistically significant.

RESULTS

Study population

In the final cohort of 5578 adult patients with mild head injury (table 2), high risk cases were less frequently males

Table 2 Clinical characteristics of patients with different level of risk of complications after mild head injury

	All cases (n = 5578)	Low risk (n = 1676)	Medium risk (n = 1200)	High risk (n = 2702)

LOC, loss of consciousness.

(51.1%), and were older. Median injury to admission time was 60 min (interquartile range (IQR) 40–110 min), without significant differences among the three risk groups.

Of the medium risk patients, 82% had amnesia (table 3), whereas 91.5% of high risk cases had one or more risk factors, in particular age over 60 years. Of the 2702 high risk patients, 705 (26.1%) were classified as high risk based only on age.

Diagnostic procedures and management

The large proportion of low risk patients (95%) were discharged without any radiological imaging after a brief observation period (median 79 min; IQR, 34–135 min). A large proportion of medium risk patients were submitted to CT, the rest having SR or no radiological imaging.

Only 65.7% of high risk patients (NCWFNS criteria⁹) were submitted to CT scan. This was due to non-systematic consideration of age as a risk factor. Indeed, only 74 of 705 patients aged over 60 had a CT scan (10.5%). When these patients were excluded from the analysis, 1700 of 1997 cases of high risk patients were submitted to CT scan (85.1%).

High risk patients were admitted for stricter observation in 38.2% of cases, the remaining being discharged after an ED observation period (median 114 min; IQR 63–189).

Post-traumatic lesions

A total of 451 injuries were detected in 327 patients (5.9%) at first evaluation. A single lesion was present in 224 (68.5%) of these patients. In addition, 17 previously undiagnosed injuries were detected after re-evaluation in 16 patients (table 4).

Fifty two low risk patients (3.1%) reattended the ED after a median of 34 h (IQR 24–48) for PCS. Only one patient, who reattended after 48 h for diffuse headache, had an undiagnosed ICH, and he fully recovered at six months without neurosurgical evacuation.

Only 26 medium risk patients (2.2%) had post-traumatic lesions at first evaluation or during the first observation period. In patients who reattended the ED (after a median of 24 h, IQR 22–72), only 49 (4.1%) had PCS.

Of the high risk patients, 301 (5.4%) had 437 post-traumatic lesions at first evaluation or during the first observation period. Among the 91 who reattended for complaints after a median of 33 h (IQR 24–60), eight (SDH, seven cases; SAH, one case) had a negative CT at first evaluation, five (SDH, three cases; ICH, one case; EDH one

Table 4 Total post traumatic lesions diagnosed and undiagnosed at first evaluation in patients at different level of risk after mild head injury

	Low risk (n = 1676)	Medium risk (n = 1200)	High risk (n = 2702)
Post-traumatic lesions at first evaluation	–	30 (2.5%)	421 (15.6%)
Depressed skull fracture	–	–	7 (0.3%)
Intracerebral haematoma	–	17 (1.4%)	203 (7.5%)
Subarachnoid haemorrhage	–	2 (0.2%)	66 (2.4%)

Epidural haematoma	–	–	2 (0.07%)
Intraventricular haemorrhage	–	–	–

case) had a negative SR, and no radiological imaging had been performed in the remaining two cases (EDH, one case; ICH, one case) (table 4).

Neurosurgical intervention

Neurosurgical intervention was performed in 71 of 5578 patients (1.3%); none had been classified in the low risk group, five were in the medium risk (0.4%), and 66 in the high risk group (2.4%). Sixty eight patients (63 in the high risk group) were submitted to neurosurgical intervention within seven days. The diagnosis was ICH (41 cases), SDH (25 cases), EDH (13 cases), DSF (4 cases), alone or in combination. In addition, SAH was diagnosed in 17 cases, IVH in two cases. Previously undiagnosed post-traumatic lesions were submitted to neurosurgical intervention only in three high risk patients (0.1%) (EDH plus ICH: one case, after 8 h; SDH: two cases after seven days, respectively. A CT scan had not been performed at first evaluation in only one of these patients (undiagnosed EDH plus ICH). He belonged to the high risk group only because of >60 years. The remaining two patients had a negative CT at first evaluation.

Unfavourable outcome

A complete follow up was obtained in 302 of 343 cases with post-traumatic lesions (88.0%). Of the remaining 41 cases, six patients died because of complications unrelated to the head trauma, seven were lost to follow up, and in 28 Glasgow Outcome Scale (GOS) was unreliable, due to either a previous disability (24 cases) or a disability unrelated to head injury (four cases).

The outcome was unfavourable in 39 cases (0.7%). All patients were high risk; 31 (79.5%) of these died during the hospitalisation for post-traumatic lesions diagnosed at first evaluation. Of these, 21 (67.7%) were older than 75 years. Only three patients (aged 95, 92, and 88 years, respectively) with undiagnosed SDH died following readmission, and no neurosurgical intervention was performed. Among disabilities, one patient remained in a permanent vegetative state and seven cases were severely disabled. The large majority of cases with post-traumatic lesions (263 cases, 87.1%) had a favourable outcome at six months; only 21 cases had a moderate disability, and 242 fully recovered.

Outcome prediction

All the variables of the proposal (GCS, clinical findings, risk factors, neurological deficits, and skull fracture) were

Figure 2 Non-parametric receiver operating characteristic (ROC) plots of the risk score obtained by logistic regression evaluating the procedure (skull fracture, Glasgow coma score (GCS), clinical findings, risk factors, neurological deficits) in identifying patients with post-traumatic lesion after mild head injury. The optimal operating point (best cut off, 2.25–2.46) of the ROC curve is also reported. AUC, area under the curve.

significantly associated with only the presence of post-traumatic lesions at univariate analysis, and were confirmed as independent factors at multivariate stepwise logistic regression (table 5). The ROC curve of the risk score for acute post-traumatic lesions, computed on the basis of the coefficients of the logistic regression (see appendix), is reported in fig 2. The accuracy in predicting post-traumatic lesions was 0.906 (0.09) and the best cut off was identified in a score value ranging between 2.25 and 2.46, having a sensitivity of 70.0% and a specificity of 94.1% (PPV 43.6%, NPV 98.0%).

Similarly, the need for neurosurgical intervention was significantly associated to only four variables (table 5), with the exception of risk factors at univariate and neurological deficits at multivariate analysis. The ROC curve had an accuracy of 0.926 (0.016) and the best cut off resulted a score value ranging between 1.81 and 2.40, with a sensitivity of 81.7% and a specificity of 94.1% (fig 3) (PPV 15.1%, NPV 99.7%).

Finally, the risk for an unfavourable outcome was not associated with clinical findings at multivariate analysis (table 5). The ROC curve had an accuracy of 0.958 (0.014), and the best cut off was a score value ranging between 3.43

Figure 3 Non-parametric receiver operating characteristic (ROC) plots of the risk score obtained by logistic regression evaluating the procedure (skull fracture, Glasgow coma score, clinical findings, neurological deficits) in identifying patients with neurosurgical intervention after mild head injury. and 3.55, with a sensitivity of 88.1% and a specificity of 95.1% (PPV 11.6%, NPV 99.5%) (fig 4).

DISCUSSION

Our data show that the variables proposed by the NCWFNS are highly accurate for predicting clinically significant outcomes in patients with mild head injury.

A large number of studies have been published to identify which patients should be managed with different options, but they largely vary in patient selection as well as in protocol design, preventing the comparison of different management regimens.²

The universal use of CT scan is not cost effective; approximately 90% of CT scans are negative, and at least 98% are negative for EDH, the event requiring immediate intervention.^{11 12} Also plain SR has been discouraged, because of its very low yield.¹⁸ The same is true for observation options: in hospital observation cannot be a routine, and home observation by a reliable observer is certainly more cost effective. The NCWFNS proposal put forward a range of practical options deemed acceptable in relation to local resources and budget constraints.⁹ In our protocol, only 2613 of 3902 (67.0%) candidates had a CT scan, the

Figure 4 Non-parametric receiver operating characteristic (ROC) plots of the risk score obtained by logistic regression evaluating the procedure (skull fracture, Glasgow coma score, clinical findings, risk factors) in identifying patients with unfavourable outcome (death, permanent vegetative state or severe disability) after mild head injury. The optimal operating point (best cut off, 3.43–3.55) of the ROC curve is also reported. AUC, area under the curve.

remaining having SR followed by a longer observation in ED. The selection was due to immediate availability of resources. The NCWFNS proposal indicates the systematic use of CT for medium and high risk patients, and supports the use of SR only in ED where CT is not available. We extended this concept to the use of SR in any circumstance when CT was not immediately available. A systematic use of CT, also in the presence of available resources, may be limited by organisational problems, and the judgment of the attending physician may be taken into account. In our study, SR was only accepted in patients who were completely intact neurologically and without clinical findings. Whichever strategy was chosen, it is unlikely that patients with post-traumatic lesions were missed. All patients who could not be adequately cared for at home were observed in hospital; patients cared for at home were advised to return in case of new symptoms, and 193 patients (3.5% of total cases) reattended for complaints. They were systematically submitted to a CT scan and in 16 of 193 cases (8.3%) post-traumatic lesions were demonstrated. Finally, patients who did not accept the observation options or who voluntarily discharged themselves were excluded. Our ED is the core of a community hospital, serving a well defined population. Also considering that a few injuries were missed, it is conceivable that they did not produce significant symptoms requiring a neurosurgical intervention, or produced an unfavourable outcome. In recent years CT scanning is progressively becoming more available out of hours as primary investigation, but the debate is about how the number of scans can be reduced. This is currently a focus of the National Institute for Clinical Excellence development group in the UK.¹⁹ The present study provides indirect evidence that the use of CT scanning may be restricted to selected groups.

However, our study was not specifically intended to validate the protocol, but to validate the predictors of outcome. The NCWFNS proposal includes a set of five variables, based on history, physical examination, and radiological imaging that were easy to interpret or to apply real time in a busy ED.⁹ The proposal has limitation as well. Risk factors have an important role, but the NCWFNS did not

specify the level of coagulopathy, drug, and/or alcohol consumption for inclusion in the high risk group. It only considered age over 60 years. Increasing age is associated with higher risk, but it is unlikely that there is a specific age threshold above which the risk sharply increases.⁹ This age limit is also a problem. Over 44% of our patients were over 60 years, and should have been managed as high risk cases. In violation of the NCWFNS proposal, we did not consider age per se a risk factor. Only one of 705 (0.1%) patients classified as high risk according to the proposal reattended with undiagnosed ICH after 48 h. There is probably room for a further simplification.

The validity of any proposal relies on clinically meaningful outcomes, important in terms of patient care and prognosis.^{11–12} The likely need for neurosurgical intervention is the most important event to predict in a mildly injured patient.^{11–12} The sample size of patients enrolled was a priori considered large enough to test the proposal, but the number of events was lower than expected for each risk group. No low risk cases were submitted to neurosurgical intervention; only five patients were operated on in the medium risk group (expected range of 12 to 36⁹) and 66 in the high risk group (expected, 162 to 270⁹). All cases were inhabitants of the health district referring to our hospital, and it is very unlikely that cases requiring neurosurgical interventions were missed. The number of injuries was as expected; and the number of deaths was not higher than expected. This might reflect a more conservative approach of neurosurgeons, without any detrimental effect on survival. The comparison of different series concerning surgical indications is frequently biased by a number of non-craniotomy procedures (like ICP monitoring),⁵ which are not used in our area in mild head injured patients. Our data confirmed the results obtained by similar studies conducted in the south of Europe.²⁰

A highly sensitive proposal would reduce the risk of an unfavourable outcome,¹² as defined by the dichotomised GOS.^{13–21–22} Telephone referred disability is an additional problem. Structured telephone interviews and questionnaires are likely to underestimate rather than overestimate the results,¹³ but have the advantage of measuring patients' awareness of clinical status.

As outlined by the analysis of ROC plots, the variables proposed by NCWFNS were accurate for the prediction of clinically meaningful outcomes, and specifically for the absence of clinical outcomes, as clearly outlined by PPV and NPV. When the ROC curves were recalculated using the three risk groups defined on the pattern of variables, the proposal maintained a fair to good accuracy. The sensitivity and specificity values for post-traumatic lesions of high versus medium/low risk patients were 92.1% and 54.4% (AUC, 0.745 (0.010)), those for neurosurgical intervention were 93.0% and 53.1% (AUC, 0.736 (0.020)), and those for unfavourable outcome were 100% and 52.3% (AUC, 0.762 (0.022)). These data are in keeping with those reported by Stiell *et al.*^{11–12} for the risk of neurosurgical intervention in a model based on five variables (GCS, suspected or open DSF, any sign of basal skull fracture, vomiting, and age ≥ 65 years), limiting the use of CT to only 32% of cases. Two additional risk factors (amnesia >30 min and dangerous mechanism) guarantee a sensitivity of 98.4% and a specificity 49.6% for predicting clinically important brain lesion, with only 54% CT required.^{11–12} These values were obtained by recursive partitioning analysis, a technique maximising sensitivity on overall accuracy. ROC plots have the advantage to allow a selection of sensitivity/specificity according to specific targets. In our series, increasing the sensitivity in the prediction of post-traumatic lesions to 96.2% reduces specificity to 48.6%, a figure similar to that reported by Stiell *et al.*^{11–12} Only a 25% specificity allows a 100% sensitivity, as reported in a seven

variable model.²³ In a low prevalence, high risk disease, the balance between sensitivity and specificity, dependent on number and type of selected variables, is difficult to set.

In conclusion, we believe that the format of the proposal may be adopted by busy physicians in the ED as a reliable, clinically sensible, potentially cost/effective tool for the management of mild head injury patients. The potential for refinement of the proposal, the usefulness of new items, and/or a different pattern of variables should also be assessed.

ACKNOWLEDGEMENTS

We are grateful to the emergency medical system personnel for helpful support. We thank the other members of the ED for data collection and participation in the study.

CONTRIBUTORS

AF conceived the study, wrote the protocol, coordinated the data collection, interpreted the results, and wrote the paper. FS contributed to interpretation of the results and critical review of the paper. GM, contributed to study design, interpretation of the results, and co-wrote the paper. A-MML carried out statistical analyses, interpretation of the results, and co-wrote the paper. MD, TI, and MS were recruited in protocol design, study coordination, data collection, and interpretation of results. AV contributed to study design, study coordination, interpretation of the results, and critical review of the paper. All authors approved the final version of the paper.

APPENDIX

Formula for calculating the scores derived from the stepwise logistic regression:

Score for post-traumatic lesion = $3.434 \times \text{SKU} + 2.463 \times (15 - \text{GCS}) + 1.461 \times \text{CLI} + 0.79 \times \text{RIS} + 0.640 \times \text{NEU}$

Score for neurological intervention = $2.404 \times \text{SKU} + 2.620 \times (15 - \text{GCS}) + 1.077 \times \text{CLI} - 0.807 \times \text{RIS}$

Score for unfavourable outcome = $2.352 \times \text{SKU} + 2.486 \times (15 - \text{GCS}) + 1.448 \times \text{RIS} + 1.076 \times \text{NEU}$

SKU: skull fracture; GCS: Glasgow coma score; CLI: clinical findings; RIS: risk factors; NEU: neurological deficits.

SKU, CLI, RIS and NEU: 0 if absent or 1 if present.
