Objective: To investigate the effect of sleep deprivation on corticospinal excitability in patients affected by juvenile myoclonic epilepsy (JME) using different transcranial magnetic stimulation (TMS) parameters.

Methods: Ten patients with JME and 10 normal subjects underwent partial sleep deprivation. Motor threshold (MT), motor evoked potential amplitude (MEP), and silent period (SP) were recorded from the thenar eminence (TE) muscles. Short latency intracortical inhibition (SICI) and short latency intracortical facilitation (SICF) were studied using paired magnetic stimulation. TMS was performed before and after sleep deprivation; EEG and TMS were performed simultaneously.

Results: In patients with JME, sleep deprivation induced a significant decrease in SICI and an increase in SICF, which was associated with increased paroxysmal activity. A significant decrease in the MT was observed. No significant changes in any TMS parameters were noted in normal subjects after sleep deprivation. The F wave was unchanged by sleep deprivation in both control subjects and in patients with JME.

Conclusions: In patients with JME, sleep deprivation produces increases in corticospinal excitability in motor areas as measured by different TMS parameters.

Sleep deprivation is the best method for provoking EEG epileptiform abnormalities^{1–4} and seizures in most types of epilepsy.⁵ Some forms of generalised epilepsy, such as juvenile myoclonic epilepsy (JME), are particularly sensitive to sleep deprivation with motor jerk phenomena.^{6,7}

Nevertheless, the mechanisms underlying the activation of paroxysmal activity, and in particular the myoclonic jerk in JME, are still debated. Some studies have attributed the activation of epileptic patterns to drowsiness and sleep,² while others have concluded that sleep deprivation has a specific activating effect on patients who remain awake during recording.⁸ In animals, sleep deprivation results in a lowering of the thresholds for electroshock convulsions⁹ and kindling¹⁰ due to a change in the balance between excitatory and inhibitory neurotransmitters.⁷

Transcranial magnetic stimulation (TMS) is a non-invasive method for exploring the excitability of the human motor cortex in vivo. Several TMS elements contribute to stimulation of the motor threshold (MT), during which the silent period (SP) may be assessed by the single pulse technique. The paired pulse method allows measurement of the so called short latency intracortical inhibition (SICI) and short latency intracortical facilitation (SICF) at short interstimulus intervals (ISIs) (1–25 ms).¹¹ Intracortical inhibition and facilitation are thought to reflect the excitability of separate populations of interneurons that are intrinsic to the cortical motor area. In fact, a reduction in cortical inhibition has been observed in different forms of epilepsy including progressive myoclonic epilepsy,^{12–14} JME,^{15–17} generalised epilepsy,¹⁸ and partial epilepsy.¹⁹ All these studies have been performed in epileptic patients when awake after normal sleep.

The important effect of sleep and sleep deprivation on cortical excitability investigated by TMS has been recently investigated in different studies with contrasting findings. In normal subjects, sleep deprivation produces a mild decrease in cortical excitability during night time that is probably related to drowsiness, although no differences in TMS values

have been observed either before or after sleep deprivation.²⁰ It has been reported that corticospinal fibres are normally activated by magnetic stimulation, while motor excitability is decreased during the different sleep stages.^{21,22} In contrast, other authors²³ have observed that in normal subjects, 24 h of sleep deprivation produces an increase in motor excitability as studied by TMS in two sessions, namely before and after sleep deprivation.

The different effects on motor excitability of sleep deprivation could be due to the different methods and objectives of the studies. Nevertheless, the sensitivity of TMS to sleep deprivation has introduced a new feature in clinical research as it allows one to evaluate hypotheses regarding changes in motor excitability in epileptic patients after activation tests that are commonly used in clinical practice. To date, no information exists on the possible changes in motor cortex excitability in epileptic patients after sleep deprivation. The main goal of the present study was to investigate the excitability of the motor cortex after sleep deprivation in patients affected by JME who are particularly sensitive to this activation test.

METHODS

Subjects

Ten patients (eight women, two men; age range 16–33 years) affected by JME were compared to 10 healthy age matched control subjects (five women, five men; age range 18–30 years). The control subjects had no history of seizures. Patients with JME had a history of seizures ranging from 2 to 7 years, and the age at onset of seizures ranged from 14 to

Abbreviations: cMAP, compound motor action potential; ISI, interstimulus interval; JME, juvenile myoclonic epilepsy; MEP, motor evoked potential; MT, motor threshold; SICF, short latency intracortical facilitation; SICI, short latency intracortical inhibition; SP, silent period; TE, thenar eminence; TMS, transcranial magnetic stimulation; VAS, visual analogue scale

18 years. All these patients reported the presence of myoclonic jerks characterised by short, sudden, arrhythmic, and symmetric muscle movements mainly affecting the shoulders and arms. Myoclonic jerks occurred frequently and briefly after awakening. Patients always consciously experienced these jerks and showed mild symptoms of absence as reported by relatives. Rare, generalised tonic-clonic seizures were also described, particularly after sleep deprivation. The EEG recording at rest was characterised by occasional bursts of polyspikes and waves on a normal rhythm background. Eight patients with JME were being treated with antiepileptic drugs (phenobarbital and valproate), while two patients with JME were not receiving pharmacological treatment during the study. The drugs were taken at the same time on each day that measurements were recorded, although we did not measure plasma levels. Neuroradiological studies (MRI) were normal in all patients. The study was approved by the local ethics committee. All individuals provided written informed consent.

Experimental design

All patients were admitted to the hospital. Sleep deprivation was experienced by both patients and controls who were all asked to stay awake from midnight until morning; napping was forbidden. Sleep deprivation was monitored by nurses. The first TMS recording was carried out between 9 and 10 a.m. on the morning before sleep deprivation and the second TMS recording was carried out at the same time on the morning after partial sleep deprivation. In all patients, the EEG recording was carried out before, during, and after each TMS recording using the coregistration EEG-TMS method.²²

Sleep deprivation in control subjects was monitored in the laboratory. Subjective sleepiness after sleep deprivation in controls and patients was evaluated in the morning before the TMS recording using a 10 cm visual analogue scale (VAS).²⁴

Magnetic stimulation

All individuals were seated in an armchair with the elbow semi-flexed; the forearm was pronated, fully relaxed, and supported by the arm of the chair. Control and conditioned motor evoked potentials (MEPs) were recorded from the right thenar eminence (TE) muscles by surface electrodes in all subjects. All individuals were asked to keep their eyes open. The amplified and band pass filtered (50 Hz to 5 KHz) EMG signal was fed into a Medelec Machine (Oxford, UK) with a sampling rate of 10 000 Hz. An auditory feedback EMG signal was produced to ensure complete voluntary relaxation of the target muscles. Trials in which voluntary EMG activity or fasciculation occurred were discarded from further analysis.

A circular magnetic coil was applied using a Magstim 200 magnetic stimulator (Magstim, Whitland, Dyfed, UK). Intracortical excitability was studied by paired TMS. For this purpose, two magnetic stimulators were connected to one circular coil (9 cm diameter) by means of a Bistim device (Magstim).

The optimal scalp position for the magnetic coil, defined as the site where moderate suprathreshold stimulation consistently yielded the largest MEP in TE muscles, was determined by moving the coil around the vertex in order to find the presumed hand area of the motor cortex contralateral to the recorded TE muscles. A constant position of the coil relative to the skull throughout the session was ensured by using a scalp cap, where the site of stimulation was marked.

The different TMS parameters used to investigate motor system excitability are described below.

(i) The MT intensity was defined as the lowest stimulator output intensity capable of inducing MEPs of at least a 50 μ V

peak-to-peak amplitude in the relaxed TE muscles in at least five of 10 trials.^{25–26}

(ii) Peak-to-peak MEP amplitudes were measured in the resting TE muscles at stimulus intensities of 110%, 120%, and 130% of the resting MT. A total of seven stimuli were delivered to each muscle in each session. The size of the MEPs was measured as a percentage of the compound motor action potential (cMAP) elicited by peripheral stimulation of the median nerve.²⁶

(iii) The duration of the SP was determined at stimulus intensities of 110%, 120%, and 130% of the MT in TE muscles performing a mean voluntary contraction of about 10% of maximum voluntary contraction. Voluntary contraction was measured using a dynamometer constructed in our laboratory. The SP was measured in the single trial rectified EMG recordings from the end of the preceding MEP to the onset of sustained voluntary EMG activity. The averages of seven trials were calculated for each stimulus intensity.²⁷

(iv) Paired TMS was performed using standardised paradigms in order to investigate SICI and SICF.¹¹ A subthreshold conditioning stimulus was set at 70% of MT and was delivered through the same magnetic coil at ISIs of 1, 2, 3, 4, 10, and 15 ms before a suprathreshold test stimulus. The test stimulus intensity was adjusted to 120% above the MT.¹¹ This procedure allows the measurement of SICI (ISI ranging from 1 to 4 ms) and SICF (ISI ranging from 10 to 15 ms). The averages of five trials were calculated for each ISI, and averages from 1 to 4 ms and from 10 to 15 ms were obtained in order to produce a single measure for SICI and SICF, respectively.

Finally, in order to evaluate spinal excitability, we studied the F wave amplitude. F responses were recorded from the TE and elicited by supramaximal stimulation of the median nerve at the wrist once every 1 s. For each set of seven stimuli, we measured the mean M wave peak-to-peak amplitude and the mean F wave peak-to-peak amplitude. Seven F responses were collected for each recording session.

EEG recording

In all individuals, the EEG recording was carried out before and after sleep deprivation as well as before, during, and after the TMS recording in order to monitor the effects of TMS stimulation on EEG activity. The EEG-TMS coregistration lasted 30 min, while each EEG recording before and after the TMS lasted 15 min. EEG recording was carried out in conscious individuals with their eyes open in order to avoid subjective drowsiness as much as possible. The EEG recording was carried out without any additional provocation (for example, intermittent photic stimulation or hyperventilation).

EEG was recorded using a 19 channel digital electroencephalograph (Micromed Instruments, Mogliano Veneto, Italy). The electrode array was in accordance with the International 10–20 system of electrode placement and was mounted on an elastic cap resistant to magnetic pulses (Micromed Instruments). A monopolar montage with a binauricular reference was used. Electrode impedance was below 5 K Ω . EEG signals were recorded with a band pass of 1.6–120 Hz and a sampling rate of 1024 Hz. Coregistration was performed by delivering the TMS using the EEG cap. The artefact of magnetic stimulation on the EEG activity lasted from 20 to 40 ms.²²

Paroxysmal activity was quantified on the basis of the number of spikes, spikes and waves, and bursts of high amplitude sharp waves on 30 min of EEG recordings performed before and after sleep deprivation. The presence and the frequency of the paroxysmal activity were considered for each recording.

Statistical analysis

The SPSS program (release 11.0.0; SPSS, Chicago, IL) was used for statistical analysis. To compare the performance of epileptic patients and control subjects for each parameter, statistical analyses were performed using Greenhouse-Geisser corrected repeated measures ANOVAs. Each ANOVA had one between-subjects factor, "group" (that is, patient or control), and a within-subject factor "time" (that is, pre and post sleep deprivation). To compare within each group and between groups, significant differences before and after the sleep deprivation, and all significant two way interactions (that is, group×time), post hoc analyses with pairwise paired *t* tests were performed.

RESULTS

Effects of sleep deprivation comparing epileptic patients and controls

There were no significant differences in most TMS parameters (SP, MEP amplitude) or in F wave amplitude and latency between controls and epileptic patients (fig 1, table 1). SICI and SICF parameters were grouped together for ANOVA analysis. With regard to the SICI, repeated ANOVA measures showed the following statistically significant main effects and interactions: the "time" main effect, with $F_{1, 18} = 5.276$, $p < 0.01$, and the group×time interaction, with $F_{1, 18} = 11.327$, $p < 0.005$. Post hoc *t* tests for the two way interaction showed that the baseline SICI values were significantly reduced in all patients with JME compared to controls ($p < 0.001$). Moreover, there was a statistically significant sleep deprivation effect in all patients with JME ($p < 0.001$) but not in control subjects.

The SICF parameter showed the following statistically significant interactions: group×time, with $F_{1, 18} = 9.174$, $p < 0.01$. Post hoc analyses showed that no significant differences were present in SICF between controls and epileptic patients. However, there was a sleep deprivation effect, with statistically significant augmentation of the SICF in the group of patients with JME ($p < 0.005$) but not in controls.

The following statistically significant effects and interactions were found in the MT parameter: the "time" main effect, with $F_{1, 18} = 63.158$, $p < 0.0001$, and the group×time interaction, with $F_{1, 18} = 90.947$, $p < 0.0001$. Post hoc analyses showed no significant differences between the two groups at baseline with respect to MT values. However, there was a statistically significant sleep deprivation effect in all patients with JME with a reduction in MT ($p < 0.001$) which was not observed in control subjects.

Eight of 10 patients with JME were being treated with anticonvulsant drugs (phenobarbital and valproate); the

remaining two patients were not under pharmacological treatment. The decrease in SICI observed after sleep deprivation was larger in untreated patients compared to pharmacologically treated patients (fig 1). Sleep deprivation did not produce any significant changes in SICI, SICF, or MT in comparison with baseline values in normal subjects (fig 1, table 1).

All individuals complained of tiredness and drowsiness at the time of the test recording after sleep deprivation. The average VAS score ranged from 2 to 3, meaning that somnolent subjects were still sufficiently alert and were capable of following the experiment instructions. No subjects had seizures after sleep deprivation. No paroxysmal activity was observed in normal subjects in the EEG recording after sleep deprivation and no significant changes were noted in the F wave amplitude.

In seven patients, the EEG recording performed before TMS showed an increase in paroxysmal activity compared to the EEG recording at baseline. The paroxysmal activity was characterised by repetitive or single bursts of polyspikes and waves. After 30 min of EEG recording, these patients showed an increase from a mean of 4 ± 1 to 13 ± 3 polyspikes bursts.

No patients complained of seizures during the TMS recording either before or after sleep deprivation and no seizures were reported in the days following the TMS recordings. Likewise, none of the patients complained of discomfort during the TMS recording either before or after sleep deprivation and no myoclonic jerks were observed in patients with JME during TMS recording. As reported in our previous study,¹⁶ most of the patients with JME reported that the proprioceptive sensations of twitching elicited normally by TMS stimulation were similar as subjective sensations to those occurring spontaneously after awakening. However, no myoclonic jerks were observed during or after TMS. No paroxysmal activity was produced or observed during or immediately after TMS during EEG coregistration. The average VAS score ranged from 2 to 3. At the time of the test recording after sleep deprivation, all individuals complained of tiredness and drowsiness but were still sufficiently alert to follow the experiment instructions. No significant differences were noted in a subjective evaluation of drowsiness by VAS between patients and control subjects.

DISCUSSION

The main finding of the present study is that sleep deprivation induced changes in patients with JME in most of the TMS variables representing different aspects of the primary motor cortex excitability. Loss of SICI, increases in SICF, and decreases in the MT were noted after sleep deprivation over the motor areas, while the indexes of spinal excitability (F waves) and neuromuscular excitability (M waves) remained unaltered.

Importantly, no changes were noted in TMS parameters in normal subjects before or after sleep deprivation in the morning, in agreement with previous studies.²⁰ The transitory decrease in motor excitability observed during the night of sleep deprivation in the previous study²⁰ was probably related to the drowsiness of the subjects, and was not addressed in the present series of experiments. In fact, a decrease in motor excitability during drowsiness and sleep has been recently documented in studies coregistering EEG and TMS in normal subjects.^{21–22}

The coregistration of EEG and TMS also allowed us to observe an increase in motor excitability in those few patients with no significant increases in EEG paroxysmal activity after sleep deprivation.

Mild, significant changes in MTs were noted after sleep deprivation in JME patients but not in controls. The MT most likely reflects the excitability of the neuronal membranes.²⁶

Table 1 TMS parameters in epileptic patients and healthy controls before and after sleep deprivation

	JME				Controls			
	Before		After		Before		After	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD
MT (%)	45*	5	40*	3	45	3	46	4
MEP amp (%)	10	4	11	3	9	5	8	3
SP 10% (ms)	40	8	42	7	41	6.5	43	7
SP 20% (ms)	80	10	75	9	79	8	80	9
SP 30% (ms)	155	13	140	9	152	8	155	10
SICI (%)	44*	8	62*	14	28	6	24	3

F wave (μV)	200	50	250	100	200	100	270	90

* $p < 0.05$.

SD, standard deviation.

Figure 1 Individual SICI and SICF recorded from the right TE muscles in 10 epileptic patients (above) and in 10 healthy controls (below) before and after sleep deprivation. The SICI is averaged across inhibitory ISIs of 1–4 ms, while the SICF is averaged across ISIs of 10–15 ms. Both are expressed as the ratio of conditioned MEP to unconditioned MEP amplitudes (y axis). The different symbols indicate the various subjects and are the same in all figures. Intracortical inhibition was reduced in 10 patients affected by myoclonic epilepsy. In healthy controls no consistent changes across the individual data were observed in either the SICI or SICF after sleep deprivation.

We assume that sleep deprivation in patients affected by JME, but in not normal subjects, had an effect on the membrane of the nerve cells that are presynaptic to the corticospinal neurone and usually excited by TMS.²⁵

Sleep deprivation did not alter the SP in either normal subjects or epileptic patients.²⁷ The SP could be the result of simultaneous excitation and inhibition and may therefore not be the most appropriate parameter for studying motor cortex inhibition.

Sleep deprivation produced loss of intracortical inhibition and mild increase in facilitation in epileptic patients but not in normal subjects.

The first (1–5 ms) phase, SICI, is thought to depend upon GABAergic mechanisms.^{26–29} The SICF is thought to result from the activation of excitatory interneurons with glutamate mechanisms.^{1–26–30} The reduction in early SICI with mild changes in SICF at rest in the present series of epileptic patients provides further evidence in support of the hypothesis that inhibitory mechanisms may be altered in epilepsy.^{6–31–33}

The increase in motor excitability after sleep deprivation could be related to changes in GABAergic mechanisms and cholinergic mechanisms, closely related to hypnogenic mechanisms.³⁴

Antiepileptic drugs can modify the TMS parameters,^{26–35–37} although in JME patients the presence of antiepileptic drugs only partially changed abnormal motor inhibition.¹⁶ No significant changes were noted in the F wave in either control subjects or epileptic patients, thus suggesting an action of sleep deprivation above the spinal level.

Nevertheless, we cannot rule out the involvement of subcortical structures as in basal ganglia pathology (for example, Parkinson's disease).³⁸ Evidence has been found for a relationship between spindle production and epileptic

activity.^{39–40} as a cortical response to intrinsic thalamocortical volleys.⁴¹ Finally, no seizures were reported in patients after sleep deprivation during or after single and paired pulse TMS.^{42–43}

In conclusion, sleep deprivation is a significant activator that produces an increase in motor excitability in epileptic patients, most likely related to a decrease in GABAergic mechanisms. The use of paired TMS as a research tool in sleep disorders merits further investigation.
