ABSTRACT

Objective Driving activity requires major involvement of executive functions. The main objective of our study was to determine whether mental flexibility and the updating of information in working memory are affected in drivers with mild to moderate Parkinson's disease (PD).

Methods The study included 25 patients, aged 58–76, with mild to moderate PD and 25 healthy controls matched for age, sex and education, with an average mileage of over 3000 km/year. Neuropsychological tests were conducted to assess global cognitive abilities, to evaluate updating (via the n-back task), flexibility (via the plus-minus task) and information-processing speed (via the Stroop test). Three different scenarios were developed on a driving simulator. Participants were asked to recall road signs (updating task), indicate the shape or colour of road signs according to road side (flexibility task) and to brake at the same time as the car ahead (information-processing speed task) while driving.

Results An updating impairment was found in PD patients in the n-back and simulator tasks; patients recalled significantly fewer road signs. No notable differences were observed between groups in the plus-minus task or in the simulator task evaluating flexibility. There was no significant difference between patients and controls in information-processing speed tasks. Regression analysis showed that the Trail-Making test (B-A) accounted for 40.7% of the variation in PD drivers' simulator task updating score.

Conclusion The updating function is clearly impaired in drivers with mild to moderate PD, while mental flexibility remains unaffected. This study demonstrates the interest of using the Trail Making Test and simulator tasks to assess PD drivers.

INTRODUCTION

Parkinson's disease (PD) is a progressive neurological disorder characterised by both motor and non-motor symptoms. Cognitive symptoms are a major feature which can appear even in the early stages of PD.^{1–2} Impairments of working memory and executive functions are frequently observed,^{2–3} as are disturbances in high-level executive functions such as planning and problem solving.^{4–5} Deficits are also described in lower-level executive functions such as mental flexibility (set shifting),^{2–6} inhibition of automatic responses⁷ and the manipulation and updating of verbal and visuospatial representations.^{3–5–8} These functions are all particularly important in novel, dynamic or demanding situations,⁹ and most driving scenarios fall into this category.¹⁰ Updating, for instance, is particularly important for refreshing information such as road

signs. Mental flexibility is also essential for adapting driving behaviour to changing contexts on the road,¹¹ where operations must be performed quickly, within a time frame.

PD patients may give up driving at some point in the course of the disease,¹² but they often continue to drive during the first decade of their illness.^{13–15} Although there are no well-established epidemiological data on the crash risk for this population,¹⁶ an increased risk of accidents has been reported in PD.^{17–18} For the above reasons, a better understanding of the relationship between cognitive and driving abilities is necessary in order to identify patients whose driving abilities may be potentially impaired.¹⁹

The main objective of this study was to determine whether executive functions such as updating of information in working memory and mental flexibility are affected in drivers with mild to moderate PD. To do so, neuropsychological tests and specific tasks using a driving simulator were used. To our knowledge, no study has hitherto investigated these functions independently using simulated driving in this population. Information-processing speed was also measured, since a slowing of this ability could well explain poorer performances in PD patients.²⁰ Our secondary objective was to examine the impact of updating and flexibility tasks on mean speed and speed variability. A further aim was to provide cognitive tools to assist clinicians in evaluating drivers with PD.

METHODS

Subjects

Twenty-five patients with PD (age range 58–76 years) and 25 healthy controls matched for sex, age, education level and driving experience were included in the study (table 1).

The sex ratio was 19 men/6 women in both groups. PD patients were recruited by a neurologist (EB) at the Department of Neurology. The following exclusion criteria were applied for patients: treatment with anticholinergic medication; global cognitive deterioration based on a score of 24 or less in the Mini Mental State Examination; moderate to severe depression based on a clinical interview and a score of 17 or more in the Beck Depression Inventory; and presence of neurological disorders other than idiopathic PD. Inclusion criteria were as follows: idiopathic PD according to the UK's Parkinson's Disease Brain Bank standards,²¹ normal visual acuity. Patients were in the mild to moderate stages of PD, based on disease duration, the Hoehn and Yahr scale and the motor section of the Unified Parkinson's Disease Rating Scale (UPDRS). Patients

Table 1 Demographic and clinical characteristics of Parkinson's disease patients and controls

	Parkinson's disease patients, n = 25, mean (SD)	Controls, n = 25, mean (SD)	Two-tailed p-value*
Age (years)	65.4 (5.2)	66.7 (4.4)	0.325
Years of education	13.9 (3.7)	13.6 (2.8)	0.937
Years of driving	45.1 (6.0)	46.6 (6.1)	0.533
Mini Mental State Examination (MMSE) score	28.1 (1.4)	29.1 (0.9)	0.006
Beck Depression Inventory score	9.0 (4.7)	6.0 (2.6)	0.008
Epworth Sleepiness Scale score	7.2 (2.9)	6.1 (3.3)	0.223
Hoehn and Yahr stage	1.8 (0.4)	—	
Disease duration in years	6.4 (5.4)	—	
Disease onset age in years	58.9 (7.7)	—	
Unified Parkinson's disease Rating Scale—motor score	14.9 (5.2)	—	
Levodopa dosage (mg/day)†	346.5 (267.7)	—

were assessed while on medication.²² Thirteen patients were rated at Hoehn and Yahr stage 1.5, 10 at stage 2, 1 at stage 2.5 and 1 at stage 3. Twenty PD patients were treated by levodopa; 9 (45%) had mild to moderate motor fluctuations. Overall, 18 patients were on dopamine agonists (pergolide, pramipexole, ropinirole, piribedil), 5 were on COMT inhibitors (entacapone), 2 on MAO inhibitors (selegiline) and 1 on amantadine. One patient was not on any medication.

Controls were recruited through different local associations for older people. They had no physical, visual or hearing impairments. There was no history or current evidence of psychiatric disorders, neurological impairment, drug or alcohol dependence, or dementia.

Participants were not taking medication known to impair driving performance, other than treatments taken by patients to control PD symptoms. All subjects held valid driving licences and were regular drivers (with a minimum annual driving mileage of 3000 km/year). None of the participants complained of decreased driving abilities. The study was approved by the local biomedical ethics committee. Written informed consent was obtained from all subjects in accordance with Helsinki guidelines.

Neuropsychological assessments

Neuropsychological testing was conducted to investigate the various cognitive processes related to driving abilities, with particular focus on updating, mental flexibility and information-processing speed.

Global cognitive assessment

Measures of global executive function were obtained using the Trail Making Test (TMT B–A).²³ The ability to inhibit an automatic response, visual memory and short-term storage capacity were assessed via the Stroop test (inhibition cost index),²⁴ Benton Visual Retention Test²⁵ and a digit span task,²⁶ respectively. Maintenance of relevant information (phonological loop), was measured using Baddeley's Working Memory digit-span task in single condition, in which participants were required to recall digits sequences of the same length for 2 min.

Updating: n-back task

This computerised task included three conditions: in the control condition (0-back), participants were asked to respond as quickly

as possible on presentation of the number 50. In the two remaining conditions, they had to evaluate the similarity of each item to the one presented n-items previously (n being a pre-specified integer (n=1, n=2)). Correct response times and errors were measured in each condition. In our study, the 2-back condition was taken as a measure of updating ability.²⁷

Mental flexibility: the plus–minus task

On the first list, participants were instructed to add 3 to each number and write down their answers. On the second list, they were instructed to subtract 3 from each number. On the third list, the participants were required to alternate between adding 3 to and subtracting 3 from the numbers. We used shift cost as a measure of mental flexibility, calculated as being the difference between mean completion times of the third list and mean completion times from the first two lists.¹¹

Information-processing speed: Stroop test

In the colour-naming condition of the Stroop test, participants had to name the colour of each rectangle as quickly as possible. This condition was designed to evaluate information-processing speed.

Driving simulator and experimental tasks

The experiment was conducted using the INRETS fixed-base simulator, a Renault Espace car with a manual gearbox, with hidden instrumentation and sensors. The vehicle has a three-screen front view with a horizontal visual field of 150° and a vertical visual field of 40° (figure 1). Before performing the driving test, subjects were invited to familiarise themselves with the simulator by driving it for 20 min. Three scenarios were developed to assess updating, mental flexibility²⁸ and information-processing speed while driving.

In the updating and flexibility tasks, the participants drove on a road with little traffic and a speed limit of 90 km/h.

Updating task

In this task (a 24 km scenario), participants were asked to recall, in any order, the last three road signs of each series while driving (free recall). They subsequently had to answer different questions about information given on the last three road signs (cued recall). Three series of four, six or eight road signs respectively varied randomly. The updating score, calculated by adding the free recall and cued recall scores, represented our updating measure (figure 2).

Figure 1 View of the driving simulator.

Figure 2 Diagram of the driving simulator updating task scenario. See details in the Methods section.

Flexibility task

There were two conditions in this task. In the condition without alternation (a 13.8 km scenario), participants had to state the shape of the road sign (rectangular, triangular, square or round) placed on the right-hand side of the road (session 1). They then had to state the dominant colour of the road sign (blue, green, red or brown) placed on the left-hand side of the road (session 2). Each session included three practice trials and 16 tests. In the condition with alternation (session 3, requiring mental flexibility), a 10.9 km scenario, participants were asked to state the shape of the road sign if it was on the right-hand side, and to indicate the colour of the road sign if it was on the left. Signs were placed alternately on the right or left of the road. The condition with alternation included four practice trials and 32 tests. Flexibility cost constituted our mental flexibility measure; this was obtained by calculating the difference between mean reaction times of correct trials in the condition with alternation and mean reaction times of correct trials from the first two sessions in which no flexibility was required (figure 3).

Information-processing speed task

This task included two conditions, one static and one dynamic. In the static condition, participants were asked to press the accelerator pedal, and to respond to the appearance of the brake lights of the car ahead, by braking as quickly as possible. In the dynamic condition, drivers had to perform the same task while driving on a straight road in a low-information environment

Figure 3 Diagram of the driving simulator flexibility task scenario. See details in the Methods section.

using a 3 km scenario. They were asked to drive at approximately 70 km/h. Each condition included three practice trials and 12 tests. The distance between the car ahead and the driver was 60 m. Brake lights lit up for 2 s, and the interstimuli interval varied randomly from 8 to 12 s. Information-processing cost, calculated as being the difference between reaction times in the dynamic condition and those of the static condition, was designed as our information-processing speed measure.

Driving speed and speed variability

Mean driving speed and speed variability (mean SD of speed) were measured in both updating and flexibility tasks. According to the literature, slow speed associated with high speed variability are indicative of decreased driving ability.^{15 29–31} A reduction in speed variability is interpreted as an adaptation of driving behaviour when a concurrent task is present.³¹

Procedure

The experimental part of the study was divided into two phases for all participants. In phase 1, they were examined by a general medical practitioner in order to verify medical inclusion criteria. In phase 2, on a separate day, neuropsychological simulated driving tests were carried out in a fixed order over a period of 3 to 4 h with two rest breaks. Driving simulator experiments lasted approximately 20 min for the updating task, 30 min for the flexibility task and 5 min for the braking task. PD patients were tested in the morning while on medication. There was approximately 1 month between neurological testing of patients and their inclusion in the study. The time between inclusion and the experiment was approximately 1 month for both patients and controls.

Data analysis

Differences between the PD and control groups regarding demographic and clinical data were analysed using an independent two-tailed Mann–Whitney U. Differences between the two groups regarding neuropsychological and driving simulator data were analysed using an independent one-tailed t test or Mann–Whitney U, depending on variable normality (Shapiro–Wilk test). In the n-back task, reaction times and errors were analysed using repeated-measure ANOVAs with group as the between-subjects factor (patients/controls), and condition as the within-subjects factor (0-back/1-back/2-back).

We used the Wilcoxon test to compare mean speed and speed variability performances between the flexibility task (condition with alternation) and the updating task. We also compared mean speed and speed variability performances in the condition without alternation to that of the condition with alternation, again using the Wilcoxon test, in order to investigate the effect of flexibility on driving performance.

Spearman correlation coefficients between UPDRS motor scores and updating scores, and flexibility and information-processing costs were calculated to ensure the absence of any association between motor functions and cognitive performances. Correlation analyses (Pearson product moment correlation and Spearman rank correlation coefficient) were used to measure the association between the neuropsychological variables and on-simulator updating scores for all participants. All significant correlated variables were then introduced into a stepwise regression analysis in order to determine which variables explain the variation in updating score for the simulator updating task for PD patients.

An α -level of 0.05 was applied to all our statistical analyses. All analyses were performed with SPSS 17.0 statistical software (SPSS, Chicago, Illinois).

RESULTS

Neuropsychological performances

In the light of neuropsychological results, the cognitive status of patients did not appear to be significantly impaired compared with controls (table 2). Global executive function (TMT), inhibition (Stroop-inhibition cost index) and verbal short-term storage (digit span) did not differ between PD patients and controls.

Updating: n-back task

ANOVA results showed that reaction times were significantly slower in patients ($538.82 \text{ ms} \pm 95.04$) than in controls ($489.70 \text{ ms} \pm 70.23$) ($F(1,48)=4.32$, $p=0.043$). However, patients did not commit significantly more errors than controls (patients: 1.91 ± 2.59 vs controls: 0.56 ± 0.72). Specifically, participants were significantly slower and committed more errors when the level of complexity increased (for reaction times: $F(2,48)=83.73$, $p<0.010$; for errors: $F(2,48)=15.53$, $p<0.001$). This was confirmed by a significant group $\times$ condition interaction for reaction times ($F(2,48)=5.35$, $p=0.025$) and for errors ($F(2,48)=5.16$, $p=0.028$). PD patients and controls did not differ in the 0-back condition for reaction times and errors. In the 1-back condition, no significant difference in reaction times was observed between the two groups, although patients committed

significantly more errors. In the 2-back condition, the mean reaction time for PD group was significantly slower than that of the control group ($F(1,48)=4.79$, $p=0.033$). Similarly, the mean error for PD group was significantly higher than in the control group ($F(1,48)=5.15$, $p=0.030$).

Flexibility: plus-minus task

Although PD patients were significantly slower than controls to complete lists in all conditions, there was no significant difference between the two groups in shift cost (table 2).

Information-processing speed: Stroop test

In the Stroop colour-naming condition, the patients were not significantly impaired, compared with controls.

Performances on driving simulator tasks

Updating, flexibility and information-processing speed task performances are presented in table 3. Significant differences were recorded between the two groups for the updating score: PD patients recalled significantly fewer road signs than controls. In the flexibility task, patients were significantly slower than controls in the condition with alternation. However, flexibility cost did not differ between the two groups. Moreover, in the information-processing speed task, while patients were significantly slower in static and dynamic conditions, there was no difference in information-processing cost between the two groups.

Driving speed and speed variability

Results for mean speed and speed variability in PD and controls during updating and flexibility tasks are presented in table 4. There were no significant differences between groups except in updating task: speed variability was surprisingly lower in patients compared with controls.

We further examined the effect of updating and flexibility tasks on driving speed and speed variability independently from disease effect. This showed that participants (both patients and

†Two patients were excluded from the analysis because their data could not be analysed.

controls) had a significantly slower mean driving speed (82.87 ± 8.07 vs 93.61 ± 11.85) ($W = -5.04$ $p < 0.01$) and higher speed variability (9.36 ± 2.77 vs 4.55 ± 2.33) ($W = -3.54$ $p < 0.01$) in the updating task than in the flexibility task (condition with alternation). In addition, in the flexibility task, also for all participants, the mean speed did not differ between the two conditions (condition with or without alternation) whereas speed variability decreased significantly in the condition with alternation ($W = -4.55$ $p < 0.01$).

Correlation analyses in PD patients

UPDRS motor scores did not correlate significantly with updating scores, flexibility cost scores and the processing cost scores. Updating scores on the driving simulator correlated significantly with the following neuropsychological variables: Stroop inhibition cost index ($r = -0.513$, $p < 0.01$), TMT (B–A) ($r = -0.560$, $p < 0.01$), plus-minus task shift cost ($r = -0.571$, $p < 0.01$) and reaction times in the three conditions of the n-back task (0-back: $r = -0.428$; 1-back: $r = 0.413$; 2-back: $r = -0.394$, $p < 0.05$). No significant correlations were obtained between Benton Visual Retention Test scores, digit span scores and TMT A scores. Subsequently, only measures which correlated significantly with updating scores were entered in the stepwise regression model. According to this model, TMT (B–A) explained 40.7% of the variation in updating score on the simulator test. The remaining variables were not sufficiently significant to be included in the model.

DISCUSSION

The main purpose of this study was to assess the extent to which executive functions such as the updating of information in working memory and mental flexibility are affected in drivers with mild to moderate PD. Our approach was original in that it attempted to examine these functions while driving with a simulator. In this discussion, we shall first of all examine the updating impairment found in PD patients. We will go on to comment on the absence of any flexibility effect and to discuss this dissociation. Finally, we will consider the clinical implications of these results in the context of driving.

Updating

Both neuropsychological and simulator tests revealed impaired updating in PD patients. In the n-back task, results indicated that the patients perform significantly worse than controls

when working memory load increases. The fact that patients are significantly impaired on the 2-back condition is consistent with previous reports.^{32–33} The results obtained on the n-back task corroborate the findings in the updating task on the simulator: patients recalled significantly fewer road signs than controls. However, the possible existence of a relationship between a deficit in updating and a slowing in information processing is not supported by the current results.³⁴ Although patients are generally slower, the results observed on the Stroop colour-naming test and in the information-processing speed task suggest that information-processing speed was not affected in mild to moderate PD drivers compared with controls. In addition, the updating deficit in PD patients is not due to decreased storage abilities. Verbal short-term storage, measured by digit span, remains intact in our patients, and this is coherent with previous results.^{1–3} Furthermore, according to Baddeley's model of working memory,^{35–37} updating appears to require two independent mechanisms: the phonological loop involving the maintenance of task-relevant information, and a central executive component. The updating deficit observed in our study cannot be explained by an information maintenance deficit: PD patients' digit span, as measured by Baddeley's Working Memory dual task, is not significantly different from that of the control group. The updating deficit would appear, therefore, to stem from a central executive dysfunction. This hypothesis is consistent with our regression analysis results. Indeed, the TMT (B–A), considered in our study as a measure of global executive function, appears to be the best predictor of updating score in the simulator for PD drivers. This means that the updating task on the simulator is closely linked to the executive system. It is worth noting that the TMT is often reported as being a good predictor of driving performances^{14–15–29–30} and driving cessation for PD drivers.¹² Our research confirms the usefulness of this test for clinicians in the assessment of PD drivers.

Flexibility

Contrary to the updating function, flexibility is found to be unimpaired in PD patients compared with controls in both the plus-minus task and the flexibility task on the simulator. A limited power due to the small sample size might explain the absence of difference between groups on tests assessing flexibility. This could also be attributed to our selective inclusion criteria. Participants were only included if they were active drivers, and most of our patients were at relatively early stages of the disease compared with those in other studies.^{6–16–38} Alternatively, our flexibility task might not be demanding enough to discriminate between the two groups. Several authors have in fact shown that an impairment in shifting only appears in PD patients when the load of attentional resources increases.^{6–15–38} The dissociation observed between updating and flexibility tends to support the conceptual view that the executive component can be fractioned.^{11–39}

Driving speed and speed variability

In addition to cognitive performance obtained on driving simulator tasks (eg, total recall score, reaction times), we analysed mean driving speed and speed variability.^{15–29–31} Interestingly, for all participants, the mean driving speed was slower, and the speed variability was higher in the updating task than in the flexibility task (condition with alternation). This result suggests poorer driving abilities in the updating task.¹⁵ This task would appear, therefore, to have a greater impact on driving performances. In the flexibility task, speed variability in both groups decreased significantly in the condition with

alternation (in which the flexibility mechanism was required). This means that both groups adapt their driving behaviour by reducing speed variability.³¹ Obviously, these results concern only speed measures; other vehicle control measures may well be reported in future research.

Conclusions and clinical implications

There is clear evidence that updating function is affected in active drivers with mild to moderate PD. According to the literature, updating is an important executive process which might be related to more complex executive functions such as goal management or planning.^{11–40} Uc *et al* have shown that in real driving contexts, PD patients experience planning difficulties which affect driving performances.²⁹ These difficulties could stem from specific updating impairment. This hypothesis could be tested in future research in order to examine the impact of the updating function in drivers with PD in real driving situations. In addition, these findings may have important clinical implications which ought to be taken into consideration by health professionals. Our work confirms that the TMT is a relevant neuropsychological assessment tool for clinicians in the evaluation of PD drivers. Moreover, the use of driving simulators could provide valuable data for predicting driving performances and for observing adjustments in driving behaviour, especially in drivers with mild to moderate PD.
