Chemical epidural abscess: case report

N. VIJAYAN AND P. M. DREYFUS

From the Department of Neurology, School of Medicine, University of California, Davis, and the Neurology Service, Sacramento Medical Center, Sacramento, California, U.S.A.

SUMMARY Spinal epidural abscess accompanies blood-borne infection, vertebral osteomyelitis, or an overlying cutaneous source of infection. This report documents the development of a non-infective epidural abscess where the inflammatory response was induced by the highly irritant contents (keratin and cholesterol) of an underlying epidermoid. This was associated with aseptic meningitis.

Since the original clinical description by Albers in 1833 and the classical anatomical study by Dandy in 1926, a number of reports and reviews of spinal epidural abscess have appeared in the literature (Heusner, 1948; Dús, 1960; Gindi and Fairburn, 1969). Similarly, subdural epidermoid cysts complicated by spontaneous or surgically induced chemical meningitis have been described (Crichtley and Ferguson, 1928; Olivecrona, 1932; Decker and Gross, 1967; Cantu and Wright, 1968). Congenital dermal sinuses which communicate with intraspinal dermoid or epidermoid cysts associated with recurrent meningitis are well-known clinical entities (List, 1941; Mount, 1949). It is the purpose of this brief communication to report a case in which an aseptic, chemically induced epidural abscess was caused by an underlying epidermoid cyst within the subarachnoid space, in the absence of a communicating sinus tract.

CASE REPORT

The patient was a 5 year old Mexican-American girl who had previously been admitted to the hospital at ages 2½ and 3 years because of febrile convulsions. Lumbar punctures were performed on both occasions. These were described as yielding normal cerebrospinal fluid.

She was readmitted to the hospital on 13 February 1969 because of fever, questionable nuchal rigidity, irritability, limping, and pain in both knees. On admission to the hospital, nuchal rigidity was no longer present and neurological examination was reported as normal. Temperature was 39°C (102.2°F). White cell count was 15,800/cu. mm with a slight shift to the left. All other laboratory examinations were normal except for a lumbar puncture which revealed normal pressure and slightly turbid fluid containing 1,842 white cells/cu. mm of which 93% were polymorphonuclear leukocytes and the rest lymphocytes.

The protein content was 145 mg/100 ml. and the sugar 20 mg/100 ml. (concomitant blood sugar 100 mg/100 ml.). A smear of the sediment and cultures were negative. The patient was treated with parenteral ampicillin and the temperature declined after four days. The patient remained irritable and pain in both knees persisted. Lumbar puncture once again revealed slightly turbid fluid under normal pressure, containing 3,500 leucocytes/cu. mm of which 91% were polymorphonuclear leukocytes and the remainder lymphocytes. Sugar was 32 mg/100 ml. and the protein content 150 mg/100 ml. Smear and cultures were negative. Blood cultures were also negative. An intermediate strength PPD tuberculin test was negative.

Clinical improvement was apparent during the ensuing days. A subsequent lumbar puncture was traumatic. The fluid contained 14,700 red blood cells/cu. mm and 190 white cells/cu. mm, of which 51% were polymorphs. The sugar content was 40 mg/100 ml. and the protein 213 mg/100 ml. Smears of the sediment and repeat cultures were negative.

The patient remained asymptomatic for a week, after which she began to limp and again complain of pain in both knees and low back. She was anorexic and irritable. While in bed, the patient tended to keep both hips and knees flexed. There were apparently no headaches, vomiting, or nuchal rigidity. The temperature had once again risen to 37.8°C (100°F). In the standing position a loss of the normal lordosis with paravertebral muscle spasm and tenderness over L3, 4, and 5 vertebral spines were noted. Kernig’s sign was present bilaterally. Passive movements of both hips and knees showed full range of motion. No weakness or muscle wasting could be detected in either lower extremity. Deep tendon reflexes were normal and symmetrical and the plantar responses were flexor bilaterally. No alteration of sensation could be elicited. Examination of cranial nerves and both upper extremities was normal. The bladder was visibly distended and the patient could void only small amounts of urine. Radiographs of the chest, spine, hips, and knees were normal. Laboratory studies revealed a
normal white count, a haemoglobin of 9·4 g/100 ml., and normal urine. Lumbar puncture showed slightly turbid fluid under normal pressure containing 267 white cells/cu. mm., of which 66% were polymorphonuclear leucocytes and the remainder lymphocytes. The protein was 238 mg/100 ml. and the sugar content 42 mg/100 ml. (blood sugar 80 mg/100 ml.). No organisms were seen on smears and India ink preparations; cultures for micro-organisms including M. tuberculosis and fungi were negative.

A few days later the patient was found to have decreased knee and ankle jerks and diminished rectal tone. By the next morning she was incontinent of urine and faeces and knee and ankle jerks could no longer be elicited. Plantar and dorsiflexion of both ankles was diminished. In order to confirm the suspected diagnosis of epidural abscess, careful aspiration of the L4-5 interspace was carried out. Two millilitres of pus were removed. This was followed by surgical exploration of the epidural space at L3, 4, and 5 vertebrae. No dermal sinus or other tract was found. A small quantity of pus and some granulation tissue were removed. The underlying dura was found to be thickened but intact. The pus revealed no organisms on either smear or cultures. Histological examination of the epidural granulation tissue showed a large number of multi-nucleated, foreign-body giant cells (Fig. 1).

The patient continued to worsen after surgery. Knee and ankle jerks remained absent and she continued to be incontinent of faeces. Cystometrographic examination revealed a neurogenic bladder. Ten days later the patient was operated on again because of continued neurological deterioration, evidenced by increasing weakness and atrophy of thigh and distal leg muscles. The epidural space was found to be free of pus; the dura was intact but appeared tense. The latter was opened opposite L3, 4, and 5 spinous processes and an oval-shaped cyst measuring 0·5 × 2·0 cm was revealed. This cyst had been draining into the subarachnoid space, causing a severe degree of adhesive arachnoiditis involving the roots of the cauda equina. The cyst was removed and some of the adhesions freed. Histological examination of the cyst revealed a typical epidermoid cyst (Fig. 2).

Postoperatively, the wound healed normally, the patient's pain disappeared, and there was no further progression of neurological signs. However, despite treatment with steroids and active physical rehabilitation the patient made a poor functional recovery.

FIG. 1. Cross-section through the cyst.

FIG. 2. Epidural granulomatous process removed at the time of the first operation. Several multi-nucleated giant cells are seen scattered throughout the field.

**DISCUSSION**

Spinal epidermoid and dermoid cysts result from ectodermal dysplasia occurring during the development of the neural tube (Walker and Bucy, 1934; Ingraham and Matson, 1961). According to List (1941) the time at which this occurs determines whether a dermoid or an epidermoid cyst develops subsequently. In the early phase of development, the dysplastic cells are 'multi-potent' and a dermoid cyst containing all of the dermal elements develops. At a later phase, the cells are 'uni-potent' and hence an epidermoid cyst develops. Trauma has been invoked as an aetiological factor in the development of epidermoid cysts in the lumbar region. According to Choremis, Economos, Papadatos, and Gargoulias (1956) and Blockey and Schorstein (1961) repeated lumbar punctures may drive fragments of epidermis into the subarachnoid space; these, subsequently proliferate and develop into an epidermoid cyst. In all of their reported cases, the cyst became symptomatic three to 10 years after the initial lumbar puncture. In the case under discussion, the first lumbar puncture was performed two and a half...
years before the onset of symptoms. It is, therefore, conceivable that the initial lumbar puncture was responsible for the cyst which was ultimately removed.

Whereas dermoid cysts have a predilection for the lumbosacral region, epidermoid cysts are evenly distributed along the extent of the spinal canal (List, 1941). When symptomatic, these cysts behave like any other intraspinal mass, causing pressure on the nerve roots. On the other hand, when the contents of a cyst discharge into the subarachnoid space, a chemical meningitis ensues. In the presence of a dermal sinus, recurrent meningitis or epidural infection may occur.

In our case, an epidural abscess developed in the absence of any visible sinus tract. We postulate that an embryologically determined cyst was inadvertently punctured during one of the initial lumbar punctures and that the cyst contents were thus allowed to flow into the epidural space, setting up an aseptic, granulomatous inflammatory process. The possibility of a small communication between the cyst and the epidural space which was subsequently sealed off by the inflammatory reaction cannot be excluded.

It is of interest to note that the material which was removed from the epidural space at the time of the first operation contained a large number of multinucleated giant cells. This ‘foreign body’ reaction may have been caused by the spillage of the cyst contents into the epidural space. Cholesterol crystals and keratinaceous material which are contained in these cysts are highly irritative in nature. The unusual combination of an epidermoid cyst accompanied by an epidural abscess in the absence of a communicating dermal sinus was responsible for the fact that the correct diagnosis was initially overlooked and that the chemical meningitis was not treated with steroids, which are reported to be highly effective in this type of meningitis.
