Radiofrequency cordotomy for the relief of spasticity in decerebrate cats

DANIEL SORIANO AND RICHARD HERMAN

From the Department of Neurosurgery, Albert Einstein College of Medicine; and Department of Physical Medicine and Rehabilitation, Temple University College of Medicine, and Moss Rehabilitation Hospital, Philadelphia, U.S.A.

SUMMARY The effectiveness of radiofrequency (RF) cordotomy of segmental motoneurone pools of the lumbosacral cord in reducing spasticity of decerebrate cats is evaluated. The need for a new form of therapy for clinical spasticity is based upon the limitations of contemporary methods, including surgical and pharmacological techniques. In man, spasticity of spinal origin may be treated effectively by intrathecal administration of hyperbaric phenol solutions. The advantages and disadvantages are described. Difficulty in controlling the lesion is emphasized. Tension and EMG-length curves of the spastic triceps surae muscle in acute and chronic animals show that RF lesions (fixed amperage and duration) of the segmental motoneurone pools reduce myotatic reflex activity in accordance with the number of segments cordotomized. Clinical examination including cinematography and electromyography complement the physiological interpretation. RF lesions of the internuncial pool induce spontaneous EMG discharges. This finding is related to similar observations of EMG discharges and alterations in muscle tone after asphyxiation of the spinal cord.

Neurological disorders often lead to exaggerated muscle tone (spasticity or rigidity) which subsequently may result in disabling patterns of motor behaviour and/or deformity.

Until recently, surgery was the principal method employed to reduce spasticity of spinal—that is, paraplegia—origin. Numerous surgical procedures, such as partial and total neurectomy, anterior and posterior rhizotomy, transverse myelotomy, lumbar-sacral cordectomy, hemicordotomy, dorsal column cordotomy, myotomy and tenotomy, to name but a few, were performed. However, the results of these surgical procedures were not, for the most part, successful in relieving spasticity. Moreover, they often led to further complications usually associated with major surgery, and frequently contributed to enhanced morbidity.

Recently, the pharmacological approach to the clinical management of spasticity has received wide attention and practice. One group of pharmacological agents are referred to as muscle relaxants.

These are centrally acting, rather than peripherally acting, drugs that at least in the experimental animal, suppress brain-stem centres and/or the internuncial pool of the spinal cord. Such central nervous system depressants initially influence the internuncial pool, considering the large number of nuclei and neuronal chains that are available to drug action (Wright, 1954). This alteration in polysynaptic activity often releases its inhibitory effects upon the extensor motoneurones, resulting in enhancement of the monosynaptic reflex (Brooks and Koizumi, 1953). Suppressants of this nature, given in large amounts, may directly inhibit cells of the motoneurone pool, which are fewer in number and, therefore, less likely to be affected by relatively smaller amounts of the drug (Wilson, 1958). It appears that spinalization abolishes tonic inhibition of the internuncial pool, leading to enhanced background of motoneurone activity and increased flexor response (Eccles and Lundberg, 1959; Herman, 1964). Thus, by altering internuncial pool excitability, these drugs can apparently suppress this background activity, thereby decreasing the excitability of the motoneurone pool (Wilson, 1958). It may be that the drugs act on the Renshaw system as well and inhibit the spinal cord by removing recurrent facilitation.

628
Radiofrequency cordotomy for the relief of spasticity in decerebrate cats

or by weakening the latter sufficiently so that it is overcome by recurrent inhibition (Wilson and Talbot, 1960). Since muscle relaxants act primarily upon the interneuronal pool (including the Renshaw system), they should have greater effectiveness in patients with enhanced polysynaptic activity—for example, subjects with spinal cord lesions—(Teasdoll, Magladery, and Ramey, 1958; Magladery and Teasdoll, 1958; Herman, 1964).

Considerable experience, both clinical and physiological, with various muscle relaxants has substantially reinforced the principle that these drugs are more effective in subjects with spinal cord lesions; such drug induced alterations in myotatic reflex activity are attributed to a reduced flexor response. However, sedation and other side-effects often accompany changes in reflex activity. Further, there is no scientific evidence that muscle relaxants enhance motor behaviour or directly depress feedback from muscle afferent nerves (Pedersen, 1962; Schwab, 1964).

An ideal muscle relaxant is a drug which, when administered orally, gives the desired reduction of exaggerated muscle tone without simultaneous decrease in voluntary power, and without side-effects such as sedation. No such substance is known at this present time.

In patients with spinal cord lesions, the application of phenol in a hyperbaric form has been found to be a very effective agent for reducing exaggerated reflex activity and improving reciprocal behaviour between agonist and antagonist motor groups (Nathan, 1955; Dimitrijević and Nathan, 1967). When used judiciously in selected cases it is considered the optimal method. Phenol solutions have both a short-term (local anaesthetic) and a long-term (destructive) effect on nerve tissue. The destructive effect is non-selective in that nerve fibres of all diameters are destroyed (Smith, 1964; Nathan, Sears, and Smith, 1965). In subjects (usually paraplegics) with severe disabling spasticity of the flexor and adductor muscle groups, intrathecal phenol solutions applied to nerve roots (preferably sensory roots) reduce exaggerated local and general reflex activity. Changes in reflex activity occur as a result of an adequate number of fibres being destroyed. The advantages of this technique are: (1) it is easy and rapid to perform, (2) it causes only minimal discomfort, (3) it can be repeated, (4) it effectively relieves spasticity in proximal motor groups for a prolonged period of time. Bladder and sphincter involvement are major disadvantages. These complications restrict its use to a selected group of patients.

The need to avoid such complications and to provide a more controllable technique for the relief of spasticity led to this investigation of radiofrequency cordotomy for the treatment of spasticity in decerebrate cats. The introduction of percutaneous cervical radiofrequency cordotomy for the relief of chronic pain has spurred much interest in stereotactic spinal cord surgery (Rosomoff, Carroll, Brown, and Sheptak, 1965; Rosomoff, Sheptak, and Carroll, 1966; Gildenberg, 1969). Both lateral and anterior approaches to the cervical spinal cord have proved successful and a similar means of access to the lumbosacral cord has been found feasible.

The studies described below were carried out to determine the feasibility of utilizing percutaneous radiofrequency cordotomy to the lumbosacral cord for the treatment of spasticity of spinal origin.

**METHODS**

In this study, 25 cats of both sexes, weighing between 3.0 and 4.0 kg, were decerebrated under ether anaesthesia at the intercollicular level. They were separated into two groups; 11 animals served as acute preparations and 14 as chronic preparations.

**ACUTE PREPARATIONS** Lumbosacral laminectomies were performed following the development of decerebrate rigidity (approximately three hours after surgery). The dura mater was incised to expose the nerve roots as they emerged from the spinal cord. The roots were identified and followed centrally to the corresponding spinal cord segment. A needle electrode, which served as both a stimulating and a lesion-inducing instrument, was introduced in the area of the ventral horn. The electrode (0.020 in. stainless steel wire, insulated by no. 50 polyethylene with 1 mm bare at the tip) was then inserted through an 18 gauge thin-walled 3.5 in. short bevel spinal needle and connected to a radiofrequency generator (Radionics 3A). The position of the electrode was monitored by stimulating the ventral horn zone with a low intensity square wave electrical impulse of 0-1 msec duration. The induced action potential (EMG) was recorded by means of a pair of silver disc electrodes placed on the surface of the gastrocnemius muscle, amplified by a Teca high gain amplification system, and recorded on a Grass oscillograph or a Tektronix storage oscilloscope. After identification of the appropriate ventral horn(s), a radiofrequency (RF) current of 40 mA was applied through the electrode for 30 to 60 seconds to only the right side of the lumbosacral cord. The ventral horn segments on the left were not disturbed. Thus, in these animals, rigidity was maintained in the left lower extremity and reduced in the right lower extremity. In control animals, the electrode was placed into similar segments but current was not applied (sham procedure).

After the RF cordotomy, the tendons of the triceps surae and tibialis anterior muscles were dissected free. The animal was placed in a prone position with the ankle and knee of each lower limb fixed. The tendons were secured to a Statham strain gauge transducer which was connected to a Grass SP1 amplifier and oscillograph. The transducer was also fixed to a micromanipulator...
which was used manually to stretch the muscle 12 to 14 mm at 2 mm increments. After each 2 mm increment, tension and EMG activity were recorded. Sustained stretch after each step was maintained for five seconds. Three recordings of total tension- and EMG-length relationships were made for each muscle in both lower extremities. After this procedure, the sciatic nerve was sectioned and the tests repeated. The resultant tension-length curves represented the passive, viscoelastic properties of muscle. The difference between passive tension and total tension indicated the magnitude of active or reflex tension induced by slow stretch of the muscle. Each animal was killed after these procedures; the spinal cord was removed and submitted for histological studies—for example, Nissl stains.

CHRONIC PREPARATIONS Parallel preparations were conducted; laminectomy and RF cordotomy were performed six weeks before decerebration. During this six week period, clinical observations of gait, sensory, motor, and bladder function were documented. Diagnostic electromyography and cinematography served to complement the clinical findings. Tension- and EMG-length findings were determined before and after the decerebration. Histological examinations of the spinal cord were made and compared with the clinical and physiological data obtained.

RESULTS

In both the acute and chronic group of animals, RF lesions were created in selective segments—for example, L7, L7-S1, L6-S1—so that each group had comparable procedures performed. Sham and bilateral cordotomy procedures served as control experiments.

A 40 mA radiofrequency current of 30 to 60 seconds duration produced lesions with coagulative necrosis and localized haemorrhages as seen in histological sections. Nissl stain of the segment showed a reduction of neurones in some areas about the anterior horn, and partial to complete absence of neurones in the anterior horn (Fig. 1). The lesions often extended to the intermediate grey matter and, at times, to some portion of the white matter. The size of the lesions was between 1 to 2 mm in the transverse plane, and 2 to 3 mm in both the longitudinal and anterior-posterior planes. Multiple lesions were usually ellipsoidal in shape in the longitudinal plane. A specimen from the lumbo-sacral portion of the spinal cord with a bilateral lesion demonstrated an almost completely selective lesion of the anterior horns.

The tension- and EMG-length relationships of the triceps surae muscle were determined three hours after decerebration of the animals in both the acute and chronic preparations. The results consistently showed that tension and EMG induced by stretch of the right triceps surae muscle were less than those of the left triceps surae muscle. The observed tension and EMG decreased as the number of segments destroyed increased (Figs. 2, 3; Table). The tension-length measurement of the left triceps surae muscle (control) always demonstrated a 'spastic' curve, in which both terminal tension and EMG were marked and in which the tension-length curve shifted to the left. In the sham operations, spastic curves were observed in both lower limbs (Fig. 3). After bilateral cordotomy, tension-length curves of the triceps surae muscles approximated those obtained by stretch of the same muscle after peripheral sciatic nerve section (Fig. 2d).

FIG. 2b. Tension-length curves after RF cordotomy of right L6, L7 segments.

FIG. 2c. Tension-length curves after RF cordotomy of right L6, L7, S1 segments.

FIG. 2d. Tension-length curves after bilateral cordotomy (L5, L6, L7, S1); note the marked alteration in tension-length curves and in EMG activity.

FIG. 2. Tension-length curve of left (— — —) and right (—•••—•••) triceps surae muscles after RF lesion of motor neurone pool segments. The difference between the left or control curve and the right or treated curve represents alteration in total stretch reflex (myotatic plus visco-elastic behaviour of the muscle). The tension-length curves of the left (— — —) and right (—•••—•••) triceps surae muscles reveal the passive, visco-elastic response of the muscle after complete transection of the sciatic nerve. The degree of myotatic activity of the respective triceps surae muscles is then viewed as the difference between the total and passive response. EMG firing patterns at 12 mm of stretch are shown for the left (A) and right (B) triceps surae muscle.
When the tension-length curves were compared with the number of segments cordotomized, some quantitative values (peak tensions, shift of the tension-length curve) could be established with respect to alterations in stretch reflex activity. A lesion of one segment, either L7 or S1, usually diminished reflex activity of the triceps surae muscle to a minimal degree—that is, 20-28%. Cordotomy of two segments (L6, L7) diminished the response to stretch further (30 to 42%) while lesions of three and four segments (L6-S1, L5-S1) showed considerable reduction in reflex activity (72 to 92%).

The magnitude in fall in active tension as a function of stretch was directly associated with a reduc-
Electromyographic records of the resting left tibialis anterior and left triceps surae muscles in the chronic preparations were usually silent. This electrical silence was also observed after a sham operation of the lumbosacral spinal cord. When the RF lesion was confined to the motoneurone pool (confirmed by histological sections) of L6, L7, or S1 segments fibrillation potentials in the triceps surae and tibialis anterior muscles were noted. However, in two animals, when the lesion was inappropriately placed in the interneuronal area with sparing of most motoneurones, sustained spontaneous action potentials appeared in both muscle groups (Fig. 4). These action potentials were continually observed during routine electromyographic examination. They were not influenced by muscle stretch. After decerebration, RF lesions were applied again to the appropriate ventral horn segments in order to suppress these spontaneous EMG discharges.

Apart from the effects of feedback from muscle and other peripheral receptors, excitability of the spinal motoneurone pool depends upon the integration of suprasegmental and intersegmental pathways upon the anterior horn cells. Suprasegmental control of spinal reflexes varies according to the anatomical level. This control of motoneurones is most likely mediated through the corticospinal and brain-stem reticular systems which apparently influence the
interneuronal processes of the spinal cord (Magoun and Rhines, 1947; French, 1960). Lesions involving these descending systems withdraw the inhibitory effects of the interneuronal link between the peripheral afferent (Ib, II, and III fibres) and the motor nuclei of the ventral horn (Eccles and Lundberg, 1959; Kuno and Perl, 1960). The intersegmental system, consisting of the ascending and descending propriospinal neurones (long and short) interconnects the spinal segments and enables the cord to integrate supraspinal and intraspinal influences, particularly at the interneuronal level (Gernandt and Gilman, 1960; Gernandt and Shimamura, 1961).

Several investigations dealing with spinal cord lesions in man suggest that segmental interneuronal activity is altered (Magladery and Teasdal, 1958; Herman, 1964, 1970). It would appear that the response of the motoneuronal pool fluctuates with the level of external influences of background activity, such as the threshold of the interneurones (Hunt and Perl, 1960). Interneuronal excitability results from withdrawal of tonic inhibition of the interneurones and from the development of recurrent facilitation in the segmental axon collateral system (Wilson and Burgess, 1962). As a result, the excitability level of both extensor and flexor motor discharges are enhanced, although flexor activity is usually most pronounced. While in some animals most descending systems influence the ventral horn cells through the internuncials, in monkey, and probably in man, the corticospinal tracts also terminate directly upon these motor cells (Lloyd, 1941; Kuypers, 1958, 1960; Landgren, Phillips and Porter, 1962). Therefore, it is possible that, in spinal cord lesions, the inhibition of motor discharges may be removed directly as well as indirectly. The effect of spinalization upon the propriospinal system also modifies the excitability between neighbouring segments and interlimb reflexes. While these connections (interneuronal) are normally depressed by the propriospinal system, they are released by spinal cord transection, thus contributing to a spread of enhanced facilitation throughout the cord (Gernandt and Gilman, 1960; Gernandt and Shimamura, 1961).

The medical management of spasticity of spinal origin must, therefore, be orientated towards attenuating motor neurone pool discharges either directly or indirectly. Indirect reduction of motor neurone pool excitability can be accomplished by suppressing background interneuronal activity—that is, by direct action on the interneuronal pool and/or by altering brain-stem reticular discharges—and by restoring the balance between recurrent facilitation and recurrent inhibition (Wilson and Burgess, 1962). Centrally acting muscle relaxants most probably function in this manner; however, their effect is not usually pronounced in patients with severe disabling spasticity in which flexor or extensor reflex behaviour is markedly sustained. When higher concentrations of these drugs are administered, anterior horn cells are suppressed directly. At such doses, however, side-effects limit their usefulness.

The enhanced level of segmental and intersegmental background activity is also maintained by peripheral afferent discharges. Spinal cord lesions suppress the inhibition of interneurones which transmit impulses segmentally from group II and group III fibres (Eccles and Lundberg, 1959). Further, after spinal cord transection, there is facilitation or removal facilitation of intersegmental and interlimb reflexes, which are activated by group I afferent fibres, leading to enhanced activity throughout the spinal cord (Gernandt and Shimamura, 1961). This altered response of the spinal cord to peripheral afferent input leads to changes in the reciprocal behaviour between muscle agonists and antagonists during stretch and during voluntary activity. The lack of reciprocal inhibition is a feature of the spinal form of spasticity as contrasted with the hemiplegic form of spasticity in which reciprocal inhibition is marked (Herman, 1970). The effect of afferent discharges on spinal cord reflexes can be modified by the intrathecal administration of hyperbaric solutions of phenol. Such solutions of phenol can lead to a non-selective, partial destruction of a number of sensory roots (Nathan, 1966). By reducing sensory inflow, background segmental and intersegmental excitation is reduced, thus decreasing motor neurone pool discharges. Alterations of these external influences on spinal cord activity often improves agonist-antagonist motor behaviour with considerable increase in reciprocal inhibition (Dimitrijević and Nathan, 1967; Herman, 1970). Additionally, the decrease in sensory input also reduces the level of autonomic hyperreflexia which may be marked in subjects with high cord lesions.

Partial destruction of the motor root with phenol is not such an effective form of treatment. It usually does not improve reciprocal behaviour between agonist and antagonist and does not sufficiently suppress peripheral afferent support of the interneuronal systems.

Peripheral neurolysis of mixed peripheral nerves with aqueous phenol solutions is not generally utilized in severe spasticity of spinal origin unless a considerable number of mixed peripheral nerves are blocked—for example, bilateral obturator and tibial nerves. Utilizing the latter technique, some investigators have successfully treated a number of patients with a moderate degree of spasticity; how-
Radiofrequency cordotomy for the relief of spasticity in decerebrate cats

However, this form of treatment is not generally recommended as a routine measure unless reduction of reflex activity of a specific motor group is desired (Morrison and Herman, 1967).

Thus, while intrathecal phendyl injection is currently the preferred method of treatment for spasticity of spinal origin, there are a number of limitations which restrict its application to a select group of patients (see introduction). These difficulties are primarily due to problems in controlling both the degree of neuronal damage of any one root lesion and the number of segments involved.

The technique of radiofrequency cordotomy of the motor pool is capable of overcoming some of the objections attributed to intrathecal phendyl administration. In decerebrate cats, a review of the myotatic reflex response—that is, tension-length curves, EMG activity, etc.—of the spastic triceps surae muscle and of the clinical examination, before and after RF cordotomy of the lumbosacral segments, reveals that regulation of motor outflow can be better achieved by means of an RF lesion with respect to the control of the degree of destruction of any one motor neurone pool and to the ability to select the number of segments necessary to reduce myotatic reflex activity. Additionally, the RF cordotomy procedure will not interfere with sacral reflex pathways of the viscerosomatic system. Despite the apparent success with RF cordotomy of the motor neurone pool, an RF cordotomy which reduces sensory inflow to segmental and neighbouring segmental motor neurone pools should be a more effective technique in suppressing exaggerated reflex activity (for reasons described above). These experiments are presently in progress.

EMG examination of the lower limbs was utilized to describe the presence and degree of denervation activity and the magnitude of stretch induced reflex activity. Spontaneous action potentials did not appear when the muscle was at rest or at a slack position. However, in two chronic animals, when an RF lesion was created in the internuncial pool rather than the motor neurone pool, spontaneous sustained EMG discharges appeared in the resting triceps surae and tibial anterior muscles. These discharges were not influenced by muscle stretch. Similar findings were observed experimentally following asphyxia of the spinal cord.

Gelfan and Tarlov (1959) developed a concept of asphyxial rigidity. This rigidity would be caused by spontaneous discharge of motoneurones made hypersensitive by the destruction of interneurones. The loss of interneurones induces a change in the subliminal fringe of the motoneuronal pool, thus creating high excitability of motor neurone discharge. According to Van Harreveld (1964), the discharge activity from the anterior horn cells can be viewed as a result of denervation hypersensitivity. Van Harreveld demonstrated that, in dogs, spinal cord asphyxia maintained for 30 to 35 minutes induces extensor tone in the hind limbs. The asphyxia is accompanied by marked destruction of the interneurones. In Gelfan and Tarlov's (1962) preparations (asphyxiation of the cord by clamping the thoracic aorta), the interneuronal destruction was not accompanied by destruction of large motor cells. It was postulated that the smaller cells of the interneuronal pool (and possibly the gamma efferents) are more sensitive to the lack of oxygen than the larger alpha cells of the motor neurone pool.

These changes lead to a clinical rigidity of the limb in both animal and man. This form of rigidity is not supported by muscle stretch nor markedly influenced by deafferentation and thus has been classified as an alpha type rigidity resulting from release or disinhibition of large motor cells (Wright, 1964).
