An anomalous origin of the middle meningeal artery

GAVIN ROYLE AND ROGER MOTSON

From the Department of Anatomy, Charing Cross Hospital Medical School, London

SUMMARY A human skull is described in which the middle meningeal artery probably arose bilaterally from the lacrimal artery. The branches of the middle meningeal vessels, however, were normal both in their position and distribution. This anomaly is a rare occurrence and is of neurological importance.

The skull, which had well-defined bony markings, was that of a 25 to 35 year old male with full dentition and was probably of Asiatic origin. The Cephalic Index was 81.2 (brachycephalic). The bones of the skull were normal and in addition there were bilateral pterion ossicles, five lambdoid sutural bones, and three parieto-occipital sutural bones, two on the right and one on the left. The foramina in the base of the skull (Fig. 1) were symmetrical and within normal limits of size and distribution with the following exceptions: there was bilateral absence of the foramen spinosum, emissary sphenoidal foramen, and foramen meningo-orbitale. The foramen innominatum was present on the right side only.

The grooves on the interior of the skull indicated that the main stems of the middle meningeal arteries arose from the lateral limits of the superior orbital fissures (Fig. 2). The origin and distribution of the vessels were bilaterally symmetrical.

The main stem of the vessel passed laterally for 17 mm, grooving the greater wing of the sphenoid, and ended by dividing into anterior and posterior divisions, which were normal both in their position and distribution (Fig. 3).

In addition to the markings of the middle meningeal vessels, accessory meningeal, anterior and posterior ethmoidal, and some small vessels supplying the anterior and posterior cranial fossae marked the skull bilaterally.

DISCUSSION

Davies and Davies (1962) state that the middle meningeal artery normally arises from the first part of the maxillary artery and enters the skull through the foramen spinosum. Its named branches are anterior, posterior, superficial petrosal, superior tympanic, branch to the trigeminal ganglion, temporal and orbital, the latter anastomosing with the recurrent meningeal branch of the lacrimal artery. The middle...
menginal veins form two principal trunks, an anterior and a posterior. The anterior either passes through the foramen spinosum to the pterygoid plexus or ends in the cavernous or sphenoparietal sinuses, forming a communication between the veins of the face and of the meninges. The posterior trunk usually passes through the foramen spinosum. The branches of the middle meningeal artery and vein accompany one another, the vein lying external to the artery. Jones (1911) states that grooves on the skull are made by the veins but indicate the position of both vein and artery. Thane (1892) states that the middle meningeal artery occasionally gives off the ophthalmic artery; rarely, the ophthalmic artery may give off the anterior division of the middle meningeal artery and, more rarely, the ophthalmic artery may give off the main stem of the middle meningeal artery itself.

Chandler and Derezinski (1935) undertook a survey of the origin and course of the middle meningeal artery in 1,200 hemi-skulls and found only a single case of the anterior division and no case of the main stem of the middle meningeal
The middle meningeal artery is common to both the middle meningeal and lacrimal arteries, explaining the normal anastomosis between them. In the adult the recurrent branch of the lacrimal artery either passes through the foramen meningo-orbitale when present or through the superior orbital fissure.

Thus, in the case described in this paper, the middle meningeal artery probably arose bilaterally from the lacrimal artery. The middle meningeal veins probably drained into the superior ophthalmic veins.

The origin and distribution of the middle meningeal vessels is of surgical importance—for example, concerning extradural haemorrhage. Knowledge of their anomalies is therefore also of importance.

This paper describes a rare anomaly of which very few cases have been documented and none previously photographed.

We would like to thank Professor T. W. A. Glenister and Dr. J. R. W. Ross for their advice and Mr. R. Barnett for taking the photographs.
