From the Department of Neurology, Royal Free Hospital, the Department of Histopathology, Royal Postgraduate Medical School, and the Department of Radiology, National Hospital for Nervous Diseases, London

SUMMARY Whipple’s disease confined to the nervous system occurred in a 36-year-old woman who presented with grand mal seizures and dementia. There was no evidence of extracerebral involvement and the jejunal biopsy was negative before treatment. Multiple enhancing lesions on CT scan progressed despite therapy with minocycline and prednisone, but resolved on treatment with tetracycline. The dementia did not progress while she was on antibiotic therapy. Whipple’s disease should be considered as a treatable cause of progressive dementia even in the absence of an abnormal jejunal biopsy.

In their review of central nervous manifestations in Whipple’s disease Pallis and Lewis1 pointed out that a variety of neurological manifestations occur, with or without systemic involvement, and that these neurological disorders are treatable. The purpose of the present report is to document a further case of Whipple’s disease confined to the nervous system with previously undescribed radiological findings, which responded to therapy.

Case report

A 36-year-old Irish housewife, presented in December 1977 with two nocturnal grand mal convulsions. She had suffered from intermittent dizziness without vertigo for the previous two years, but had no other symptoms. On admission, she was noted to be vague and apathetic with poor memory for recent events but with no other physical signs. Skull radiograph, gamma scan, ultrasound, and plain computed tomography (CT scan), (fig 1) were normal, but her EEG showed epileptic activity in the right hemisphere. She was discharged on treatment with phenytoin and phenobarbitone. Within four months she was readmitted, having become confused and disoriented in space, with a euphoric mood and further memory loss. She had lost 12 kg in the previous nine months, but there was no history of steatorrhoea, change in bowel habit, abdominal pain, arthralgia, or fever. On examination there was no hypopigmentation, lymphadenopathy, or abdominal tenderness and no neurological abnormality on formal testing. Psychometric testing confirmed a moderate generalised dementia with an overall IQ of 82.

Fig 1 December 1977. Normal plain scan.

Investigations
ESR 3 mm/h, Hb 12.9 g/dl. White cell count 7.1 × 10⁹/l; normal differential. ANF and anti-DNA antibodies were negative. Populations of circulating T and B cells were normal, with normal function, and serological tests for fungal antibodies and JC and SMV-40 polyoma viruses were negative. Serum phenytoin and phenobarbitone levels were within the normal range. Faecal fats were normal at 6.3 mmol/day (normal less than 18 mmol/day). The serum folate was low (2.2 μg/l; normal 2.5 μg/l−5 μg/l). Serum albumin and serum iron levels were normal. The WR was negative in serum and cerebro-spinal fluid. The CSF was examined on three occasions, and the pressure and white
cell count were always within normal limits. However, the total protein (normal 0.1 g/l-0.4 g/l) rose from 0.45 g/l to 0.9 g/l in two months prior to treatment, and then fell to 0.45 g/l after two months treatment with minocycline. The corresponding IgG fractions (normal less than 10% of total protein) were 0.093 g/l (20.7%), 0.159 g/l (17.7%) and 0.057 g/l (12.7%). There was no evidence of sickle-particle-containing cells in the CSF. No fungal antigens could be detected and bacterial (including acid fast) and viral cultures were negative. Jejunal biopsy was normal.

A CT scan (fig 2) showed regions of low density involving both temporal lobes with multifocal enhancement and minimal mass effect.

A right temporal craniotomy (Mr Richard Hayward)

revealed abnormally white and thickened superior and middle temporal gyri. Biopsy through the abnormal brain showed that thickened and gliotic areas were interspersed with soft grey tissue. Histologically there was a subcortical zone 2-3 mm in diameter of tissue rarefaction with oedema and proliferation of protoplasmic astrocytes, accompanied by numbers of large rounded foamy cells with small dark nuclei and granular cytoplasm staining strongly with PAS. Smaller rounded PAS-positive cells were also present (fig 3). Elsewhere in the biopsy white matter oedema, astrocytic proliferation, and scattered PAS-positive macrophages were seen, and scattered small foci of tissue rarefaction were present in both grey and white matter. No sickle-cell particles or intact bacilli could be detected in formalin-fixed material by electron microscopy.

A presumptive diagnosis of cerebral Whipple's disease was made and the patient was treated with minocycline 100 mg twice daily, and prednisolone 40-60 mg daily for three months, as well as anti-convulsants. Satisfactory minocycline levels were obtained 3 hours after taking the medicine (1.3 μg/ml serum and 0.54 μg/ml CSF). During this time dementia did not progress and fits did not recur. Repeat psychometric testing showed no significant deterioration, and the EEG improved. However, a repeat CT scan (fig 4) showed increased numbers of enhancing lesions. The antibiotic therapy was changed to tetracycline 250 mg four times a day and because of side effects, prednisolone was reduced to 15 mg/day and stopped completely after three months. Five months after starting this regime, her condition remained static and a further CT scan (fig 5) showed complete resolution of the enhancing lesions but moderate cerebral atrophy. Two years later having taken tetracycline continuously there has been no significant deterioration in her condition although she remains disorientated with short term
Fig 4 November 1978 (a) and (b) similar sections to those in fig 2; more widespread enhancing lesions bilaterally. The lateral ventricles have slightly enlarged. (c) higher section showing additional enhancing lesions.

Fig 5 April 1980 (a) and (b) similar sections to those in figs 2, 4 (a) and (b). The low density is much less pronounced and there is no longer any abnormal enhancement. The ventricles have enlarged further and there is some widening of the sylvian and interhemispheric fissures owing to moderate cerebral atrophy.
Whipple's disease confined to the nervous system

memory loss and is unable to lead an independent existence.

Discussion

Since Pallis and Lewis reviewed published cases of Whipple's disease with neurological involvement in 1974, there have been a number of further reports so that by 1980 the same authors were able to propose that dementia, external ophthalmoplegia and myoclonus of the head, trunk and limbs constituted the central element of the syndrome of neurological involvement in Whipple's disease. Meningitis and myopathy have also been documented.

In the present patient, the diagnosis of Whipple's disease was suggested by both clinical and laboratory findings. Dementia in the fourth decade arrested by antibiotic treatment (see below) was strongly suggestive of Whipple's disease. The biopsy findings were also fully consistent with the diagnosis. Failure to demonstrate sickle-particle containing cells first described by Siarecki or intracellular bacilli in the cortical biopsies from patients with proven Whipple's disease had been noted elsewhere. The only atypical feature was the patient's sex: only five of 34 cases of Whipple's disease with neurological involvement published up to 1978 were female.

Clinically Whipple's disease may be confined to the nervous system, but even so involvement of the intestines can almost always be shown by biopsy. Absence of histological change in the gut prior to treatment has only once been reported previously. Finelli et al described two patients with Whipple's disease with predominantly neuro-ophtalmic manifestations and absent gastrointestinal symptoms, one of whom had had a negative jejunal and liver biopsy prior to treatment. The patient of Romanul et al had been treated with short courses of steroids and various antibiotics over four years, and although at autopsy no gut involvement was demonstrated, no jejunal biopsy was performed prior to treatment or during the course of the illness. In the present case there was no clinical or biochemical evidence of extracranial involvement (the one minimally low serum folate level could have resulted from the concurrent administration of phenytoin). The negative jejunal biopsy prior to therapy confirms that small intestinal biopsy cannot be considered reliable in excluding Whipple's disease in patients with suggestive neurological symptoms.

CT scans in previous reports of central nervous system involvement in Whipple's disease have either been normal or revealed cerebral atrophy only, though in one report an area of altered density in the right temporo-parietal cortex was also demonstrated. Our series of four EMI scans over 15 months show the evolution of multiple masses of attenuation similar to and lower than that of normal brain which enhanced with intravenous Conray. They exerted minimal mass effect and were associated with progressive cerebral atrophy which persisted following resolution of the lesions on antibiotic therapy. The lesions were widely distributed throughout the cortical and subcortical regions of both cerebral hemispheres, but although brain stem syndromes may be a feature of Whipple's disease, no infratDaniel B. Holmes, Robert C. Maitland, Anthony J. Leach, Joseph J. Young, and Brian J. Holland

neurological involvement was demonstrated.

The CT scan therefore may prove a useful adjunct in the diagnosis of Whipple's disease of the central nervous system and for following response to treatment. Assessment of the effect of therapy on the neurological consequences of Whipple's disease is not easy because of the slow progression of the disease and the possibility of spontaneous fluctuations. Available reports of the effects of antibiotic treatment on the course of neuro-Whipple's disease are summarised in the table. Patient 1 received tetracycline for only 18 days in the terminal stage of his illness, and in the case described by Schmitt et al, a patient with gaze palsy, polydipsia, and dementia one month's treatment with iv penicillin and chloramphenicol failed to improve her symptoms significantly. In the remaining cases antibiotics were given from between six months and five years. In these patients gaze palsies and nystagmus were the signs most responsive to treatment, improvement occurring in four out of five patients, and in the remaining case, patient four, treatment with tetracycline was followed by deterioration of the gaze palsy, which was arrested on substitution by chloramphenicol. Dementia was arrested in all five cases and confusional states were improved in three others. Myoclonus improved in two out of four cases, stabilised in one and deteriorated in the fourth despite a change in antibiotic therapy. Papilloedema remitted over one year in the one case where it was observed although steroids were used for the initial two weeks as well as tetracycline.

Hypothalamic syndromes developed despite maintenance treatment with tetracycline or doxycycline in three patients. One patient died, and in the remaining two patients the symptoms persisted despite substitution by chloramphenicol in one case, and chloramphenicol, ampicillin and Septrin in the other. There was only one case of deterioration of neurological symptoms despite prolonged appropriate therapy. In patient 5 right-sided myoclonus progressed on oral penicillin and was not improved by...
substitution of chloramphenicol and erythromycin. In our patient, minocycline which has a similar spectrum to tetracycline, was initially preferred because of its higher penetration into the CSF. Only 10% of tetracycline crosses uninfamed meninges, whereas CSF levels of 30% of those in the serum can be obtained following administration of oral minocycline. No clinical deterioration occurred and the CSF protein and IgG fraction fell, but the progression of the CT scan lesions followed by their resolution with tetracycline suggests that minocycline may not be effective in Whipple’s disease.

Steroids appeared to play no useful part in the treatment of our patient and have not been much used in the treatment of parenchymal disease in the other cases reviewed. However in one report a patient with meningitic Whipple’s disease failed to respond to antibiotics but was controlled satisfactorily with prednisolone.

The present case illustrates the value of radiological and pathological investigations in establishing a diagnosis of Whipple’s disease of the nervous system. Since it is a potentially treatable cause of progressive dementia, in which an increasing number of reports show the value of antibiotics, every effort should be made to establish an early diagnosis.

Our thanks are due to Professor J Newsom-Davis for allowing us to report his patient, to Miss M Rubeck, of the Drug Information Centre, Royal Free Hospital and to Miss D Burston for helping us to prepare the manuscript.
