Appearing and disappearing CT scan abnormalities and seizures

PK SETHI, BR KUMAR, VS MADAN, V MOHAN

From the Neurological Centre, Army Hospital, Delhi, India

SUMMARY A group of patients presenting with seizures (focal or generalised) and abnormal CT scans who, on follow up, showed complete resolution of the CT scan changes, without any treatment other than anticonvulsants, are described.

Seizures may be due to idiopathic epilepsy or be symptomatic of an underlying disorder which may be revealed by computed tomography (CT). Possible scan abnormalities include: congenital disorder (birth injury and infarction), trauma, tumour, infection (abscess, encephalitis, tuberculosis, toxoplasmosis, cysticercosis), vascular disease and degenerative disorders. These CT abnormalities are expected to persist, increase or leave some evidence of the original lesion in follow up scans unless some specific treatment is given in treatable cases. We report patients presenting with seizures in which initial CT scans were abnormal, but on follow up CT scans these abnormalities had disappeared with no specific treatment except anticonvulsants.

Materials and methods

Eleven cases, seen in the epilepsy clinic of our neurological centre in the past year had initial CT scan abnormalities that completely disappeared over the next 6 to 24 weeks with no treatment except anticonvulsants.

Case reports

The table summarises the clinical data from eleven cases. In the following three cases the sequence of events surrounding the seizure and the follow up are described.

Case 1
A 14-year-old boy, product of term delivery with a history suggestive of slight hypoxia at birth, was well till the morning of 26 June 1983, when he had clonic movements of the right toes with Jacksonian extension on the right side, later becoming generalised with loss of consciousness. On 10 August, he had three similar episodes of focal seizures starting on the right side but with no generalisation or loss of consciousness. On 26 August he had another such episode following which he had weakness of right foot. There was a partial right foot drop, and the right knee jerk was brisk. Fundi were normal. Blood count, urinalysis, skull, chest and thigh radiographs, blood chemistry and awake EEG were all normal. CT scan on 26 August 1983 showed a small area of increased attenuation value in the left parietal parasagittal region with significant perifocal oedema (fig la). He was given phenobarbitone 30 mgm morning and 60 mgm at night. The weakness of the right foot and leg completely disappeared over the next two weeks and he remained seizure free. A repeat CT scan on 1 February 1984 was normal (fig lb).

Case 2
A 4½ year-old boy, a product of a normal term delivery was well till the evening of 7 September 1983 when he had clonic motor seizures involving the left arm. He had six or seven seizures in one hour and developed mild postictal weakness of the left arm. Temperature was 99.8°F and fundi were normal. Blood count, urinalysis, blood chemistry, skull radiography and CSF examination were normal.
### Table: Summary of clinical findings

CSF done — NAD
Individual declined admission but had follow up scans in another hospital. Repeat CT scan 16 Apr 83. Complete clearance.

EEG showed generalised bursts of spike/slow wave discharges bilaterally. CT scan on 14 September 1983 showed a low attenuation lesion in the right fronto-parietal region. The child was given phenobarbitone 30 mgm twice a day and has remained asymptomatic. A repeat CT scan after 20 weeks showed complete disappearance of the earlier CT findings (fig 2 ab).

**Case 3**

A 34-year-old female presented with generalised seizures on 16 October 1983 with postictal prolonged confusion and postictal weakness of the right hand which recovered in the next four hours. She had another generalised seizure on 18 October 1983 with postictal prolonged confusion and vomiting. She continued to have left sided headache and projectile vomiting. Examination was normal except that she looked apprehensive, depressed and had repeated yawning. Fundi were normal. A diagnosis of late onset seizures with Todd's paresis on the right side was made and an intracranial space occupying lesion was suspected. She was put on phenobarbitone 30 mgm morning and 60 mg at night. Blood count, urinalysis, skull thigh and chest radiographs were normal. EEG showed slowing in the left sided leads (monopolar run) with occasional spikes. CT scan showed a high attenuation lesion with perifocal oedema in the left posterior temporal region. Her headache and vomiting subsided in a week and she became asymptomatic. In view of vomiting and headache, an intracranial space occupying lesion was strongly suspected and she was given steroids initially for a week. She became asymptomatic and repeat scan eight weeks later showed gradual clearance of the lesion, so it was decided to follow the patient with repeat CT scans. CT scan 24 weeks later showed complete clearance of the lesion (fig 3 ab).
after seizures, which subsequently disappeared. What are the clinico-CT scan correlates of these attenuations, what is their pathology and what does their disappearance imply?

It is their disappearance without any specific therapy (except anticonvulsants) which is intriguing. It can be concluded that whatever the underlying pathology or pathophysiological changes responsible for the appearance of these lesions, the process is ultimately reversible. Therefore, congenital disorders, tumours, and degenerative disease are unlikely causes. Trauma also can be excluded as there was no history of head injury. The clinical setting and results of investigations and follow up also strongly argue against trauma, vascular diseases and infection.

Several studies⁸-¹⁰ are available dealing with CT scans in patients with various type of seizures. Gastaut and Gastaut,² reported findings of CT in 401 of 500 consecutive patients with epilepsy. 90% had normal CT and were classed under primary generalised epilepsy, while the rest had abnormal CT scans so were classed as secondary epilepsy. With organic lesions, (tumour, trauma, ischaemia and infec tions etc.) CT was considered to have markedly increased the ability to establish the aetiology. In another series,⁷ 150 patients with seizure disorder were analysed in detail. Of these 60 patients had abnormal scans. These abnormalities included atrophy (focal 13, diffuse 20), porencephaly (4), hydrocephalus (5), vascular abnormalities (6), infarction (6), and neoplasm (6). In these series⁸-¹⁰ not a single case of seizures with disappearing CT scan attenuation was reported.

Theoretically some of the cases of the present series may be due to infarction or rupture of a small angioma. Gastaut et al⁹ emphasised that Jacksonian seizures may herald Sylvian infarctions, as revealed by computed tomography. Out of a population of 942 adult epileptics examined with CT they found Sylvian infarction in 17 patients without any prior history of cerebrovascular accident. In most of these cases vascular occlusion was confirmed by carotid angiography. In the majority, however, there was post-ictal neurological abnormality for hours or days and in one third of the cases there was persistence of neurological deficit and/or Jacksonian seizures. In none of our cases except one with focal deficit present, and this subsequently disappeared. Further, in all Gastaut's cases there was CT scan evidence of low attenuation in areas corresponding with Sylvian infarction. In the present series the involved areas was not necessarily Sylvian and in some cases there was increased as well as low attenuation. Furthermore, the complete disappearance of the CT abnormalities in our patients differs from the CT scan changes due

Discussion

Over one year we encountered 11 cases with CT abnormalities (both low attenuation and mixed)
Appearing and disappearing CT scan abnormalities and seizures

The possibility of cryptic malformation must be considered. These are commonly present with intracranial haemorrhage which was not present in our cases. Further, although CT scan may not reveal these cryptic vascular malformations (microangioma), the resultant haematoma points out to the underlying pathology.

The disappearance of CT scan attenuations without any specific therapy excludes most forms of infective pathology. Cysticercosis or tuberculosis as a cause of seizures is not so uncommon in this geographical region, but neither is likely to be the cause of the CT scan abnormalities discussed here, because the latter disappeared without specific therapy. Bhargava and Tandon, studied in CNS tuberculosis in 55 cases and described a special group of 17 cases. This group of 17 patients, mostly children and young adults, presented with focal seizures with or without generalisation or associated postictal deficit but without evidence of raised intracranial pressure. On CT scan they had small disc or ring lesions. Antituberculous treatment appeared to clear the lesion on the CT scan promptly.

In view of the above discussion one wonders whether the responsible pathological lesion may not be structural but functional. Seizures may produce cerebral oedema. Meera, Goulatia and Bhargava in CT analysis of 525 patients reported 20 cases of seizures of late onset with or without papilloedema but with no focal neurological deficit, which were reported to have diffuse white matter oedema varying in absorption values from 5–15 HU and with small midline ventricles. Focal low attenuation areas seen in CT scan in our cases corresponded very well with the focal seizures and may be explained by postictal oedema akin to postictal EEG slowing. Their disappearance after appropriate anticonvulsant therapy with control of seizure may also support this hypothesis of postictal oedema. But how does one explain high attenuating lesion surrounded by low attenuated area in some of these cases? Moreover, we have encountered patients presenting with a status epilepticus with CT scans which are normal. Several reports have not described any CT scan changes in seizures per se.

Accordingly, the changes we have described may not simply be the result of focal seizures. Prior to CT scanning, such focal seizures might be attributed to missed tuberculoma or cysticercosis, which could have escaped detection using cerebral angiography or pneumoencephalography. The CT scan findings, and the subsequent recovery, do not suggest such diagnoses. Alternatively, the changes described could be a form of focal encephalitis, perhaps peculiar to this region.

In conclusion, if a patient presents with seizures and the sort of CT scan findings discussed here, without signs of raised intracranial pressure or CT scan evidence of mass effect, it appears wise to wait and repeat the CT scan instead of starting prolonged antituberculous therapy or subjecting him to invasive procedures and surgery.

We are grateful to Maj Gen JM Grover, AVSM, the Commandant, Army Hospital, for constant encouragement and the Director General, Armed Forces Medical Services for permission to publish this article.
