SUMMARY Cytokeratins were studied by immunocytochemical techniques at light and electron microscopy on 12 normal pituitary glands, 30 pituitary adenomas and three craniopharyngiomas. The results are presented in relation to clinical and biochemical features and new information on the subcellular localisation of cytokeratins in pituitary cells is discussed.

Intermediate filaments (also known as 10 nm filaments) are proteins which form part of the cytoskeleton in almost all vertebrate cells.1 Biochemical and immunological analyses have enabled classification into five major groups, of which the cytokeratin class is normally found in epithelial cells of both keratinising and nonkeratinising types.2,3 In man, 19 different cytokeratin polypeptides have been identified with molecular weights ranging from 40,000-70,000 daltons.2 In squamous epithelia these polypeptides may aggregate into bundles with other proteins to form keratin tonofilaments.1 Antibodies raised against cytokeratin polypeptides have been usefully employed in diagnostic immunocytochemistry.1,3–6 Cytokeratins are known to occur in cells of the normal pituitary gland and several polypeptide species have recently been described in some classes of pituitary adenomas.7–9 We report the results of a light and electron microscopic immunocytochemical investigation of cytokeratins in the normal fetal and adult human pituitary gland and in pituitary neoplasms, comparing the immunocytochemical findings with the results of clinical and endocrinological studies.

Materials and methods

Normal pituitary glands were obtained at necropsy from five male and five female patients (age range 18–67 years) who had died suddenly with no clinical history of pituitary or other endocrine dysfunction. Normal fetal pituitary glands were obtained at necropsy from one male fetus (gestational age 27 weeks) and one female fetus (gestational age 38 weeks) who were anatomically normal stillbirths following spontaneous abortions. Surgically resected tissues were obtained from 30 pituitary adenomas from 13 male and 17 female patients (age range 18–72 years) and three craniopharyngiomas from one female and two male patients (age range 16–32 years). Material for light microscopy was fixed in 10% buffered formol saline (pH 7·0) and embedded routinely into paraffin wax. Sections were cut at 5 μm in thickness and stained by conventional histological techniques.

All sections for immunocytochemistry were dewaxed and endogenous peroxidase activity blocked using 0·5% hydrogen peroxide in methanol for 10 minutes. The sections were then incubated in 0·05% trypsin/0·1% calcium chloride (pH 7·8) at 37°C for up to 30 minutes. Antisera dilutions and all washes were carried out in TBS-buffered saline (5 mmol Tris HCl [pH 7·6] plus 137 mmol NaCl). Staining for anterior pituitary hormones (Growth Hormone [GH], Prolactin [PR], Adrenocorticotrophic Hormone [ACTH], Thyroid Stimulating Hormone [TSH], Follicle Stimulating Hormone [FSH], and Luteinising Hormone [LH]) were performed by the peroxidase-antiperoxidase (PAP) technique10 using a monospecific polyclonal antibody for each hormone (Dakopatts Pituitary Kits K514 and K517, Mercia Brocades Ltd, Weybridge, Surrey). Staining for high subunit molecular weight cytokeratins was performed by the PAP technique10 using a polyclonal antibody (Dakopatts A575, Mercia Brocades Ltd, Weybridge, Surrey) at a dilution of 1:200. Negative controls for all polyclonal antibodies were performed using normal rabbit serum. An indirect immunoperoxidase technique was used to demonstrate low subunit molecular weight cytokeratins using the monoclonal antibody PKK1 (Lab Systems (UK) Ltd, Uxbridge, Middlesex) as follows:

1. Incubation with monoclonal antibody at 1:200 dilution (30 minutes).
2. Rinse twice in TBS.
3. Incubation with rabbit antimouse peroxidase-conjugated IgG (Dakopatts, Mercia Brocades Ltd, Weybridge, Surrey) at a dilution of 1:100 (30 minutes).

Address for reprint requests: Dr J W Ironside, Department of Neuropathology, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF, UK.

Received 25 February 1986.
Accepted 1 April 1986
Three washes in TBS (each 3 minutes).

The reaction product was visualised using 0·05% diaminobenzidine tetrahydrochloride and 0·01% hydrogen peroxide in 50 mmol Tris HCl buffer (pH 7·6).

All the PAP stained sections were counterstained in haematoxylin before being dehydrated and mounted for microscopic examination. Serial sections were cut from the normal pituitary glands and alternate sections stained for cytokeratins and each of the six anterior pituitary hormones. Sections of normal human skin were used as positive controls for high subunit molecular weight cytokeratins and sections of a human basal cell carcinoma were used as positive controls for low subunit molecular weight cytokeratins. Cytokeratin immunoreactivity for each neoplasm was recorded on a scale from 0 (absent) to ++ + (abundant) without prior knowledge of the results of hormone immunocytochemistry.

Material from surgically resected pituitary neoplasms was fixed for electron microscopy in 2% glutaraldehyde and post fixed in osmium tetroxide before processing into Emix (EMscope Labs Inc, Ashford, Kent). 1 μm sections were cut and stained with Toluidine Blue. Ultrathin sections from selected areas were cut and stained with Lead Citrate and Uranyl Acetate. For immunoelectron microscopy ultrathin sections of embedded tissue were cut and mounted on copper grids. An immunogold technique was performed as follows:

1. Wash in 10% hydrogen peroxide (20 minutes).
2. Three washes in distilled water (10 minutes each).
3. Incubate in normal goat serum diluted 1:30 in 70 mmol TBS (pH 7·2) containing 0·2% bovine serum albumin (30 minutes).
4. Incubate overnight at 4°C in monoclonal antibody PKK1 in a 1:50 dilution in TBS (pH 7·2) containing 0·2% bovine serum albumin.
5. Two washes in TBS (pH 7·2) containing 0·2% bovine serum albumin (each 10 minutes).
6. Incubate in TBS (pH 8·6) containing 1% bovine serum albumin (10 minutes).
7. Incubate in goat antimouse IgG G20 (Janssen Pharmaceutica, Beersse, Belgium) diluted 1:5 in TBS (pH 8·6) containing 1% bovine serum albumin at room temperature (80 minutes).
8. Wash in TBS (pH 8·6) containing 1% bovine serum albumin (5 minutes).
9. Two washes in TBS (pH 7·2) containing 0·2% bovine serum albumin (each 10 minutes).
10. Two wash in distilled water (each 10 minutes).
11. Lightly stain in Uranyl Acetate and Lead Citrate (approximately 5 minutes).

Negative controls were performed by both omitting the primary antibody and substituting a monoclonal antibody to glial fibrillary acidic protein (GFAP) (Sanbio BV, Netherlands) in the method above. GFAP is known not to occur in hormone secreting cells of the adenohypophysis.11

The grids were examined and photographed on a Corinth AE1 electron microscope. The density of immunolabelling with PKK1 over the cytoplasm, fibrous bodies and nucleus in sparsely granulated GH adenomas was calculated by the method of Bendayan et al12 and compared with controls for each case.

### ImmunobLOTS

Fresh normal human anterior pituitary tissue obtained at necropsy was stored at −70°C until just prior to use. The tissue was homogenised in electrophoresis sample buffer (0·25M Tris HCl, pH 6·8, 1% SDS, 20% glycerol, 1% mercaptopethanol), boiled for 5 minutes and any insoluble material removed by centrifugation. The soluble extract was applied to a 9% SDS-polyacrylamide gel for electrophoresis. Molar weight markers of M, 25,700–76,000 (BDH Chemicals Ltd) were run simultaneously. Transfer of polypeptides to nitrocellulose sheets was carried out overnight by the method of Towbin et al.14 The blot was incubated with the monoclonal antibody PKK1 at a dilution of 1:250 and the peptides identified by the antibody were visualised by the alkaline phosphatase method of Blake et al.15

### Clinical studies

The site and approximate size of each neoplasm was recorded at surgery. Anterior pituitary hormones were measured pre-operatively in the serum of all patients by radioimmunoassay. Patients with ACTH secreting adenomas had urinary free cortisol estimations performed by radioimmunoassay on preoperative 24 hour specimen collections. Fresh tissue from each pituitary adenoma was sent to Dr Keith Mashiter, Hammersmith Hospital, London, for cell culture and pituitary hormone radioimmunoassay of culture supernatant.

### Results

#### Light microscopy

The results of immunocytochemical staining for anterior pituitary hormones on the 30 pituitary adenomas are listed in table 1. Two of the growth hormone adenomas contained cells with immunoreactive prolactin and three of the prolactin adenomas contained cells with immunoreactive growth hormone, but in each case the number of cells containing the secondary hormone was small (approximately 5%). The immunocytochemical diagnosis was confirmed in each case by electron microscopy using the diagnostic criteria of Kovacs, Horvath and McComb.16 Electron microscopy also enabled the diagnosis of oncocytoma to be made in one case. Staining for anterior pituitary hormones in the intrasellar crano-

pharyngiomas was negative. The distribution of the various hormone containing cells in the normal adult and fetal pituitaries was in accordance with previously published observations.\textsuperscript{17,18}

Low subunit molecular weight cytokeratins were detected in many cells in the normal adult and fetal adenohypophysis using the monoclonal antibody PKK1. Comparison with adjacent sections stained for anterior pituitary hormones showed that the cells containing the most immunoreactive cytokeratins were of the growth hormone and prolactin types. Staining was usually present throughout the cytoplasm of these cells, but in some GH cells appeared to be aggregated in the centre of the cell adjacent to the nucleus. Most of the ACTH cells also contained low subunit molecular weight cytokeratins but showed a variable intensity of cytoplasmic staining (fig 1a and b). None of the cells containing FSH, LH and TSH appeared to contain low subunit molecular weight cytokeratins in the cytoplasm. Positive staining was seen in occasional follicular structures in the adenohypophysis containing colloid-like material and within the flattened cuboidal epithelium lining cystic structures within the pars intermedia (fig 2). The remainder of the pars intermedia and neurohypophysis showed no staining.

The results of immunocytochemical staining for cytokeratins in the pituitary neoplasms are listed in table 2. In the GH adenomas, many cells contained large intracytoplasmic aggregates of immunoreactive cytokeratins located close to the nucleus (fig 3a and b). This pattern of staining was most evident in neoplasms classified as sparsely granulated GH adenomas on electron microscopy. A smaller number of cells within these neoplasms showed a diffusely positive staining reaction. All the PR adenomas contained cytokeratins in a variable proportion of cells, usually

Fig 3 (a) PAP preparation for GH in a sparsely granulated GH adenoma (x 720). (b) Many of the cells in the sparsely granulated GH adenoma contain focal intracytoplasmic collections of cytokeratins (PKK1 x 600).

with diffuse cytoplasmic staining (fig 4). Only one of the ACTH adenomas showed positive staining which was present in occasional cells (fig 5). The TSH, FSH/LH, and non secretory adenomas and the onco-

cytoma all gave a negative staining reaction (fig 6).

All three craniopharyngiomas contained both low and high subunit molecular weight cytokeratins which were most readily visible in areas of squamous and basaloid epithelium (fig 7). High subunit molecular weight cytokeratins were not detected in the pituitary adenomas or in cells of the normal adenohypophysis, but were present within occasional follicular structures in the pars intermedia. The cells of the neurohypophysis gave a negative staining reaction.

Electron microscopy

Immunogold staining for cytokeratins in GH adenomas showed deposition of gold particles over
Immunolocalisation of cytokeratins in the normal and neoplastic human pituitary gland

the fibrous bodies in the sparsely granulated GH adenomas (fig 8a and b). Staining of centrioles, mitochondria and granules within these structures was negative. Gold deposition was also present over the heterochromatin close to the nuclear membrane and over nucleoli (fig 9). Quantitative studies confirmed the positive reaction for the 10 nm filaments within fibrous bodies, but also demonstrated a significant difference between the density of immunolabelling over the nucleus and cytoplasmic immunolabelling (table 3). In PR adenomas gold particles were also deposited over fibrillar structures within the cytoplasm which corresponded to 10 nm filaments. In the craniopharyngiomas gold particles were deposited over keratin tonofilaments and 10 nm filaments within the epithelial cells (fig 10). No significant gold deposition was found within the cytoplasm of cells from the remaining groups of pituitary adenomas. Staining for GFAP was negative in all the neoplasms.

Immunoblots

Four major bands of Mr between 56kD and 40kD were identified on protein immunoblotting of normal pituitary gland using PKK1 (fig 11).

Clinical studies

The results of pituitary hormone measurements in vivo and in vitro are listed in table 4 together with the age and sex of each patient, the site and approximate size of each neoplasm and the degree of immunoreactivity for low subunit molecular weight cytokeratins. No relationship was found between the latter and the age and sex of the patients or the size and site of the neoplasms. In patients with PR adenomas there appeared to be a general inverse relationship between cytokeratin immunoreactivity in the neoplasm and hormone levels in the serum in 8/9 cases. No such trend was found for patients with GH adenomas, nor was there any correlation between cytokeratin immunoreactivity and urinary free cortisol levels in patients with ACTH adenomas. In vitro estimations of hormone productions bore no relationship to cytokeratin immunoreactivity in GH, PR or ACTH adenomas.

Discussion

Nineteen cytokeratin polypeptides have been identified from different human epithelial tissues. No individual tissue has been found to contain only one variety of cytokeratin polypeptide and most epithelia show a complex mixture of various polypeptides. The monoclonal antibody used in this investigation recognises four cytokeratin polypeptides which are present in many epithelial tissues and neoplasms. Immuno- blots of normal human adenohypophysis with PKK1
showed four main cytokeratin polypeptides of Mr 40–56kD. By comparison with other published data these probably represent cytokeratins 11, 16, 18 and 19. The polyclonal antibody used in this study recognises high subunit molecular weight cytokeratins (predominantly 56kD and 64kD) which were not detected in the normal adenohypophysis or pituitary adenomas. Only limited information on the specific polypeptide constituents of pituitary cytokeratins has therefore been obtained. These may be identified in future by the use of monoclonal antibodies of more restricted specificity.

The results of immunocytochemistry using PKK1 on the normal pituitary gland and pituitary adenomas are similar to those in the smaller series of Höfler et al. who used an antibody of different specificity and did not examine fetal pituitary glands, TSH adenomas or oncocytomas and did not perform immunoelectron microscopy. The absence of immunoreactive cytokeratins in normal pituitary TSH, FSH and LH cells is reflected by a relative lack of intermediate sized filaments in these cells on electron microscopy. In contrast, cells secreting GH, PR and ACTH frequently contain such filaments. It is interesting to note that positive staining for cytokeratins was seen only in cells secreting peptide hormones, while those secreting glycoprotein hormones exhibited negative staining. This may reflect qualitative and/or quantitative differences in the cytokeratin polypeptide constituents between these groups of cells which might be related to differences in intracellular hormone metabolism.

Fig 9  In a sparsely granulated GH adenoma, gold granules are present over the nucleus, confined to heterochromatin on and close to the nuclear membrane (Immunogold PKK1 x 45,000).

Cytokeratins have recently been demonstrated within ACTH cells exhibiting Crooke's hyaline change. We have been able to demonstrate cytokeratins within ACTH cells in normal adult and fetal pituitary glands, but positive staining was present in only 1/4 ACTH adenomas studied. Höfler et al have demonstrated immunoreactive cytokeratins at light microscopy in 3/3 ACTH adenomas, using a monoclonal antibody reacting with intermediate subunit molecular weight cytokeratins (principally 48 kD). Neumann et al have suggested that the quantity of immunoreactive cytokeratins in ACTH cells may be inversely related to levels of cortisol in the serum. No such relationship was found in this study, nor did cytokeratin immunoreactivity in ACTH adenomas correlate with the levels of urinary free cortisol in 24 hour specimen collections or ACTH production in vitro. Similarly, no relationship between cytokeratin immunoreactivity and hormone levels in vitro or in vivo was found in patients with GH adenomas. In patients with PR adenomas, however, there was a general inverse relationship between cytokeratin immunoreactivity and serum hormone levels in 8/9 cases. This trend is of interest in view of the suggested role of intermediate filaments in hormone granule assembly and release, and merits further study. No relationship between hormone levels in vitro and cytokeratin immunoreactivity was found; this would perhaps be better investigated using immunoperoxidase techniques for cytokeratins on the cells in culture.

The pattern of cytokeratin staining at light micro-

Fig 10  Deposition of gold granules is present over epithelial tonofilaments in a craniopharyngioma (Immunogold PKKI x 15,000).

Fig 11  Polypeptide bands in extract of anterior pituitary as revealed in a PKKI Immunoblot. Four major peptides (arrows) are seen between 40–56kD. The numbers refer to the M, of marker proteins (76kD ovotransferrin, 66kD bovine serum albumin, 45kD ovalbumin, 25.7kD chymotrypsinogen A).
scopy in GH adenomas suggested that cytokeratins were in some way related to the fibrous bodies occurring in sparsely granulated GH adenoma cells. The results of immunoelectron microscopy confirmed this suggestion since gold deposition was visualised within these fibrillary structures. The functional significance of fibrous bodies is unknown. We have observed fibrous bodies within a paraganglioma arising in the cauda equina which also showed positive focal intracytoplasmic staining for cytokeratins. Similar structures have been noted to occur in bronchial adenomas which also contain immunoreactive cytokeratins. It therefore seems that fibrous bodies are non-specific structures which contain cytokeratins and occur in a variety of neoplasms which secrete peptide hormones. The consistent finding of cytokeratins within nuclear heterochromatin on immunoelectron microscopy was an unexpected result which has not previously been reported in pituitary cells. A recent study on cultured hepatoma cells has demonstrated that cytokeratin polypeptides are associated with nuclear DNA at filament binding sites or near the nuclear lamina. Similar associations in pituitary cells might account for the observed pattern of gold deposition on immunoelectron microscopy in this study. Traub et al have suggested that cytoskeletal proteins may have a functional relationship with DNA involving control of gene expression. Further work is required to analyse the precise nature of such cytokeratin-DNA associations and to investigate their functional possibilities.

We thank Dr Keith Mashiter, Department of Medicine, Hammersmith Hospital, London for permission to use the results of hormone assays performed on cell cultures in his department, and Dr S O Waarm, The University Medical Centre, Leiden, Holland for his generous gift of a monoclonal antibody to GFAP. We are grateful to Mr B Barker, Mrs S Porter and Miss J Edwards for technical assistance, and to Mrs P Kirk for typing the manuscript. Dr Royds is supported by Wellcome Trust Grant No 11353/1.5. Financial assistance from the Swann Morton Foundation is gratefully acknowledged (Special Trustees for the Former United Sheffield Hospitals Grant No 303).
