SUMMARY A prospective study of acute cerebrovascular disease in a community of about 105,000 people is reported. The study protocol combined rapid clinical assessment of patients with accurate diagnosis of the pathological type of stroke by CT or necropsy, whether or not they were admitted to hospital. The study population was defined as those people who were registered with one of 50 collaborating general practitioners (GPs). Referrals to the study were primarily from the GPs though, to ensure complete case ascertainment, hospital casualty and admission registers, death certificates and special data from the Oxford Record Linkage Study were also scrutinised. Six hundred and seventy five cases of clinically definite first-ever in a lifetime stroke were registered in four years yielding a crude annual incidence of 1.60/1,000 or 2.00/1,000 when adjusted to the 1981 population of England and Wales. The age and sex specific incidence rates for first stroke showed a steep rise with age for both sexes. The odds of a male sustaining a first stroke were 26% greater than those of a female. Ninety one cent per cent of patients were examined in a median time of four days after the event by a study neurologist and 88% had cerebral CT or necropsy.

Over the last 25 years there have been many studies of stroke incidence throughout the world. The methods used in community-based studies have varied from detailed retrospective case note reviews (for example Rochester, USA12), through cohort studies (such as Framingham, USA7 and Hisayama, Japan9) to prospective stroke registers in defined populations (for example, Tilburg, Holland8 and Shibata, Japan4) and despite the methodological difficulties of measuring stroke incidence accurately, the magnitude of the clinical, social and economic problems associated with stroke has been well established. Studies of Caucasians in Europe and North America have shown crude annual incidence rates for first-ever in a lifetime stroke (hereafter referred to as first-ever stroke) of between 1.5 and 2.5 per 1,000 though the time-trend data from Rochester show a steady decline over several decades. All studies have shown a steep rise in incidence with increasing age. The major risk factors for stroke (hypertension, transient ischaemic attack (TIA), heart disease and diabetes mellitus) have been identified repeatedly, albeit with varying relative and population attributable risks. However, for clinical purposes more accurate and detailed epidemiological data are needed since stroke is not a single pathological entity. If effective treatments are to be developed, more attention must be focused on identifying and studying the outcome of pathologically homogeneous groups.

The Oxfordshire Community Stroke Project (OCSP) was established to determine the incidence,
risk factors and outcome of first-ever stroke and TIA in a population unbiased by hospital admission or outpatient referral practice. We attempted to obtain a computed tomographic (CT) scan or necropsy on every patient to establish the pathological type of stroke and to enable accurate clinico-pathological correlations to be made. The present communication describes the study methods and presents the basic details of both the study population and the patients with first-ever stroke. Future communications will deal with the incidence and outcome of the pathological subtypes of stroke and also the incidence and prognosis of TIA.

Methodology

Study population

This comprised all patients who were fully registered with 50 General Practitioners (GPs) based in 10 health centres who collaborated in the study (see acknowledgements). In the UK, patients register with a GP who provides their primary health care and, when necessary, refers them for specialist advice. The GP receives all relevant information about specialist consultations and hospital admissions even if these do not occur locally. Thus the record held by the GP forms a lifelong record of all medical events (at least since the establishment of the National Health Service (NHS) in 1948) as well as recording details of each consultation with the GP (including blood pressure recordings, blood counts etc.) This individual record is transferred to a new GP if the patient moves residence. The practices who collaborated in the study were chosen if they were (a) in Oxfordshire (b) had an accurate age-sex register (ASR) of all patients registered with them (c) were willing to notify all patients with possible acute cerebrovascular disease to the study and (d) were enthusiastic to collaborate. The GPs provided primary health care for both urban and rural communities (fig 1) and since they all accepted a full range of patients onto their lists the study population was not restricted to any particular socio-economic group. A census of the ASRs was performed in 1981 and again in 1986 and the average value of the numbers registered at these times, in 10 year age bands according to sex, was used as the denominator for the study. The results of the censuses were validated by comparing them with the data available for the age bands 0–64, 65–74 and 75+ years from the independent records of the local Family Practitioner Committee (FPC) which are used to determine the remuneration of GPs. It was impractical to use the FPC figures themselves since these records were not computerised and were split into the above age-bands only.

Duration of the study

Registration of patients began on 1 November 1981 and continued until 31 October 1986. Partly because of problems in obtaining continuous funding and partly to allow interim analyses to be performed, the registration of cases of stroke was suspended between 1 November 1984 and 31 October 1985 though the registration of patients with TIA and the follow up of patients already registered continued during this time. Registration of stroke and TIA patients finally ended on 31 October 1986 though the referral of patients and surveillance of admission books etc continued for a further two months to ensure the registration of all patients whose stroke or TIA occurred on or before 31 October 1986. Therefore, the study registered patients with first-ever stroke over a period of four years whereas patients with TIA were registered over five years. The follow up for non-fatal events and assessment of handicap and disability will continue until 1989; mortality follow up for all patients still alive at that point will continue indefinitely via the NHS central registry at Southport.

Case ascertainment

The collaborating GPs notified the study office of any patient whom they thought might have had an episode of acute neurological dysfunction caused by cerebrovascular disease irrespective of from whom or where the patient obtained further medical care. Patients who suffered a first-ever stroke whilst temporarily away from Oxfordshire but who were registered with a collaborating GP were included. Patients...
A prospective study of acute cerebrovascular disease in the community

who were not fully registered with a collaborating GP at the time of their stroke (for example patients who were visiting Oxfordshire and who registered temporarily after the event) were excluded. A liaison GP in each practice regularly checked with colleagues to ensure that all relevant patients had been referred. The study team maintained frequent personal contact with all the GPs and our research nurses visited each practice at least once a week. A monthly newsletter was sent to all collaborators and GPs received a report on each of their patients referred to the study.

The admission and casualty registers of each hospital in the Oxford area were checked frequently to identify patients who had attended or been admitted without their GPs knowledge. The Oxford Record Linkage Study (ORLS) enabled all patients with a given diagnosis who died in, or were discharged from, a hospital in the Oxford region to be identified. The ORLS provided lists of patients with diagnoses coded to the International Classification of Diseases (9th Revision) rubrics 430 to 438 inclusive and rubric 342. Finally, copies of the death certificates of all residents of Oxfordshire were examined and copies of necropsy reports obtained.

Patient assessment
The patients were assessed as soon as possible after the event by a study neurologist (PS, JB, MD, CW) either in hospital, in a special outpatient clinic or at home. In addition to a standard neurological history and examination, an estimate of pre-stroke handicap and disability was made. The GP and hospital medical records were reviewed to check details of previous illness. A particular search was made for evidence of previous cerebrovascular events and to obtain data on any risk factors documented before the stroke. If a patient died very rapidly we attempted to obtain an eye witness account as well as using information recorded in the GP and hospital notes.

Definitions
Stroke was defined as rapidly developing clinical symptoms and/or signs of focal, and at times global (applied to patients in deep coma and to those with subarachnoid haemorrhage), loss of cerebral function, with symptoms lasting more than 24 hours or leading to death, with no apparent cause other than that of vascular origin (after Hatano). A TIA was defined as an acute loss of focal cerebral or ocular function with symptoms lasting less than 24 hours and which after adequate investigation was presumed to be due to embolic or thrombotic vascular disease. Patients were only included in the study if they had had a clinically apparent first-ever stroke or TIA.

Pathological diagnosis
We attempted to obtain a CT or necropsy examination in every case. In view of the possible risks CT was only performed with intravenous contrast if clinically indicated, initially using an EMI 1007 160 × 160 matrix scanner and, from early 1984, a Siemens Somaton DR1 scanner. CT scans were reported without knowledge of the clinical details of the stroke by the study neuroradiologist (AM).

Investigations
Whenever possible the following investigations were performed: full blood count, erythrocyte sedimentation rate, blood urea and electrolytes, glucose, cholesterol, triglycerides, syphilis serology, electrocardiograph and chest radiography. Many patients had an echocardiogram performed as part of a parallel study.

Follow up
All cases were followed prospectively. Our research nurses personally interviewed survivors in their place of residence at 1 month, 6 months and 12 months and then annually from the time of the stroke, using a standardised questionnaire designed to detect recurrent cerebrovascular and cardiovascular events. If a recurrent stroke was suspected the study neurologist re-examined the patient. The nurses administered a number of simple rating scales to all patients which were designed to measure disability and handicap. At various times more detailed information on functional ability, activities of daily living, psychological and social functioning and the impact on the chief carer were recorded on consecutive series of patients. This information formed the basis of a number of substudies which will be reported independently. Details of the use of health care resources and placement were recorded throughout the study. If the patient died, all available medical records were reviewed and a necropsy obtained whenever possible to ascertain the cause of death.

Data collection and analysis
All data were collected on precoded forms and entered onto the University of Oxford ICL 2988 and Digital VAX computers. They were analysed using the SPSS package. The confidence interval of odds ratios were calculated according to Miettinen. The pooled odds ratio and confidence interval of that ratio for age and sex differences were calculated using the method of Yusuf et al.

Results
The results of the 1981 and 1986 ASR censuses of the study population are shown in table 1. The study population derived from the ASRs was 1.1% (95% CI 1.0-1.2) less than that from the FPC in 1981 and 2.3% (95% CI 2.2-2.4) greater in 1986. Figure 2 compares the age and sex distribution of the OCSP population with that of England and Wales in 1981.

Over the five years 1818 patients were notified to the study, 1306 with suspected stroke and 512 with...
suspected TIA. After clinical assessment by a study neurologist 682 were considered to have had a first-ever stroke (of whom seven [1%] were later excluded because non-vascular pathology at a site appropriate to the clinical features was detected by CT or at necropsy—vide infra) and 184 an incident TIA. The commonest reasons for exclusion of patients referred with suspected stroke were that the event was not the first-ever stroke, that the patient was only a temporary resident in Oxfordshire or that they had non-vascular cerebral pathology. Amongst patients referred with suspected TIA the commonest reason for exclusion was the lack of clear evidence of focal neurological dysfunction. Patients with focal epilepsy, isolated vertigo, transient global amnesia and migraine were also frequently referred as possible TIA.

The number of patients registered with a first-ever stroke over each of the four years was 168, 160, 187 and 160, a total of 675. There were 357 (52.9%) females and 318 (47.1%) males. The source of first referral of these patients was the GP in 571 (84.6%), hospital admission book searches in 62 (9.2%), ORLS in 11 (1.6%), death certificate searches in 12 (1.8%) and other sources in 19 (2.8%). The ORLS and death certificate searches proved useful only in identifying the few patients who had their stroke whilst in hospital after being admitted with some other condition or who had died whilst away from Oxfordshire.

A study neurologist examined 615 of 675 (91.1%) patients. The interval from onset of symptoms to assessment is shown in fig 3, the median time being 4 days. Of the remaining 60 patients, 49 (82%) were dead at the time of first notification to the study and a further eight (13%) died after notification but before the study neurologist was able to visit. Only three of 675 (0.4%) patients refused to be examined; data on the clinical features were extracted from the GP and hospital records in these cases.

Amongst the 675 patients with a first-ever stroke 542 (80.3%) had CT performed. The reasons for not obtaining a CT scan were: rapidity of death in 44 (6.5%), the patient was too ill to transfer for the scan in 62 (9.2%), refusal by the patient or their relatives in 16 (2.4%) and miscellaneous reasons in 11 (1.6%). Eighty seven of the 133 (65.4%) patients not having CT were over 75 years of age. Of the 200 patients who have died so far, 77 (38.5%) have had a necropsy examination of whom 54 (27%) had not had CT. Therefore, only 79 of 675 (11.7%) patients had neither CT nor necropsy. Seven patients (1%) had subarachnoid haemorrhage confirmed by lumbar puncture alone. Seven patients amongst the 682 (1%) thought to have had a stroke on clinical grounds alone were shown subsequently by CT or necropsy to have non-stroke pathology: two had a primary cerebral tumour, two had metastatic cerebral deposits and three had a subdural haematoma.

The crude annual incidence of first-ever stroke was 1-60/1,000 (95% CI 1.48–1.72) and 2-00/1,000 persons when adjusted by age and sex to the 1981 population of England and Wales. The age- and sex-specific incidence rates for first-ever stroke with confidence intervals are shown in fig 4 and detailed in table 2. The

OCSP incidence rates are compared with those from other studies in Fig 5. Figure 6 shows the odds of sustaining a first stroke according to age and sex compared with the odds of dying from ischaemic heart disease.16

Discussion

The increasing financial constraint on health care budgets worldwide is likely to focus the attention of health planners and physicians on conditions such as stroke which place a heavy burden on both the individual and the community.17 Accurate epidemiological data on incidence, prevalence and outcome are required to plan future services and plan controlled trials of new treatments. In order to be accurate an incidence study should (a) be prospective (b) use a large, representative population whose structure is known accurately (c) obtain complete case ascertainment (d) have early detailed neurological assessments and (e) have a high proportion of cases with confirmed pathology. Few studies have been able to satisfy the majority of these ideals, thereby limiting the utility of the data.7

There are features in any health care system which are particularly well suited to certain types of research. The British National Health Service (NHS) system is
particularly suited to epidemiological studies since over 98% of the population is registered with a GP of their choice who is informed of any contact between a patient and the medical profession. Defining the study population in terms of patients registered with a particular set of GPs allowed sampling of patients from a wider, and thus potentially more representative area than might be studied if the denominator had been defined geographically. The problem of "cross-boundary" medical care which might arise because of the reputation of a particular physician or institution, the provision of special services, or the more rapid assessment of patients at a hospital outside the study area was also avoided. Previously, in order to circumvent this problem, relatively isolated communities have been studied (for example, Faroe Islands) but the populations have usually been too small for accurate stroke incidence studies particularly of the different pathological types of stroke. Such isolated communities may also have unusual characteristics which limit the extent to which any results may be generally valid. Our practices, though not chosen at random, provided primary health care for the range of rural and urban communities present in Oxfordshire. Although detailed socio-economic data were not available, it is likely that our study population was representative of Oxfordshire as a whole which has a slightly higher socio-economic status than the average for England and Wales. The age and sex structure of our population was broadly similar to that of Oxfordshire and England and Wales as a whole. By collaborating with all the GPs in a number of health centres we negated any tendency for certain types of patient (such as young mothers or elderly patients) to register preferentially with any individual GP.

There are relatively few studies where a population census of the relevant geographical area has been performed at the same time as the study is taking place; more often extrapolations from previous census data are used (for example Rochester). By performing a census of the ASRs at the beginning and end of the study period we were able to identify changes in the study denominator. There was a net increase of 5-6% in the population during the study period, the result of a marked increase in the numbers of young people and a small decrease in those over 65 years of age. Whilst neither the ASR nor the FPC records can be assumed to be 100% correct at any given time since deaths, births and changes of address take a number of months to be processed, the small discrepancies which we found suggest that the ASRs in the study practices were well maintained and that it was reasonable to base the study population on these figures.

Our results show that GPs can be an extremely reliable source of referral. There were very few instances where a GP appeared to know that a patient had had a stroke but did not notify the study. The large number of patients assessed by the study team but not considered to have had a first-ever stroke or TIA reflected a deliberate policy of the OCSP to encourage GPs to refer all possible cases. A more selective referral policy might have led to patients with more unusual presentations of cerebrovascular disease not being registered. It is important to assess cases of "TIA" as well as "stroke" since at least 7% of patients had an event classified as a stroke by our standard definition but which had been labelled as a TIA either by a GP or hospital physician.

The proportion of patients with stroke admitted to hospital in different countries varies widely. Some authors claim or infer, without much justification, that virtually all strokes are admitted to hospital in their own region and that they are therefore representative of all strokes occurring in the community. In Oxfordshire, only 54% of patients with first-ever stroke were admitted to hospital and in other UK studies admission rates of 40% to 70% have been reported. Aho et al noted that in the European centres of the WHO study only 75% of patients were admitted to hospital. In Japan, especially amongst the elderly, the admission rate may be even lower, a trend that was also noted in New Zealand. We have shown that cases with primary intracerebral haemorrhage (PICH) are more likely to be admitted than those with cerebral infarction (CI) and patients with milder clinical deficits (and consequently a lower case fatality rate) are more likely to remain at home. However, secondary stroke prevention is, potentially, of most benefit to this latter group. Any failure to detect such cases may distort the natural history and influence the perception of how feasible any trial of treatment aimed at secondary prevention might be. The accurate comparison of stroke incidence rates in different countries is impossible unless studies can demonstrate that they have detected most of, if not all, the cases.

Using the various checks in our study we are confident that we achieved virtually complete case ascertainment.

The major advantage of hospital-based studies is that they can make detailed neurological assessments from the time of admission and at frequent intervals thereafter. The logistics of our study permitted only a single assessment by a study neurologist, but the median delay from onset to assessment of only 4 days meant that accurate data was obtained about the acute phase of the strokes. The few patients assessed more than 2 weeks after their stroke were often those who were admitted to hospitals whilst they were away from Oxfordshire; in these cases clinical details were also obtained from the original admission records.

Although the technological advances in the last 15 years, particularly CT, have improved the accuracy of
A prospective study of acute cerebrovascular disease in the community

diagnosis of different pathological types of stroke, such facilities still tend to be orientated towards
patients who have contact with hospital based
physicians. Community-based studies are not biased
towards any particular stroke type but previous
studies have either not described the use of CT or have
used this investigation in a minority of cases. Many
have used only clinical criteria to distinguish CI and
PICH in the majority of patients yet this is known to be
inaccurate.29,30 The 88% CT or necropsy rate satisfied
the original aims of our study. It is unlikely that this
proportion can be significantly increased in UK
practice since we were aware of a reasonable re
tance to transport very frail, elderly people to hospital
to have CT, particularly if death was imminent and the
scan was unlikely to alter their management. Also
there was a reluctance on the part of GPs to press for a
necropsy in such cases.

The very low proportion of cases who presented
with what was considered to be a stroke on clinical
grounds yet were found to have some other lesion on
CT confirms the reliability of the clinical diagnosis
of "stroke."31 Also, it makes it unlikely that non-vascular
pathology was responsible for the neurological symp
toms in those patients who were assessed but did not
have CT or necropsy.

Crude annual incidence rates have little value other
than establishing the general magnitude of the clinical
problem of stroke. We would predict from our results
that about 99,000 people will have a first-ever stroke
each year in England and Wales. Our data show that
the age- and sex-specific incidence rates continue to
rise steeply with increasing age even amongst the most
elderly which confirms the findings of the Auckland
study.27 Presenting the incidence rates for the age
groups 75–84 years and 85+ years separately allows
more confident projections to be made when consider-
ing the marked demographic changes that will occur
over the next 50 years. Figure 5 shows that the rate of
increase of stroke incidence with increasing age
appears similar in Europe, North America, Asia and
Australasia and no striking geographical variations are
apparent.

The technique of pooling odds ratios15 to calculate
the excess odds of either sex sustaining a first-ever
stroke prevents undue emphasis being placed on
groups with large denominators but a small number of
events. The excess odds of a male sustaining a first-ever
stroke of 26% (95% CI 7% to 47%) are similar to
those from the Tilburg study2 when calculated in a
similar way (+18%, 95% CI 1% to +41%) though
lower than those in Rochester12 (66%, 95% CI 44% to
91%). The massive excess odds of males dying from
ischaemic heart disease (fig 6) between the ages of 35
and 55 years is not mirrored for stroke though the
subsequent reduction of excess odds in males with
increasing age is seen.

In summary, we think that the original aims of the
study which were to see all new cases of stroke and TIA
in a representative population unbiased by hospital
admission, record detailed clinical information and
obtain confirmation of the pathological type of stroke
have been fulfilled. The patients described above will
form the basis of further reports on the incidence and
outcome of various pathological subtypes of acute
cerebrovascular disease in the community.

This work was supported by grants from the Medical
Research Council and the Chest, Heart and Stroke
Association. We thank the participating general prac-
titioners and all consultants who allowed us to study
their patients, the practice receptionists and nursing
staff who helped in many ways and the voluntary car
drivers of Oxfordshire who provided invaluable help
transporting patients. We gratefully acknowledge the
assistance of Drs P Sheldon and P Anslow
(neuroradiology), M Esiri, M Squier, E Ilgren and M
Rossi (neuropathology), J A M Gray (community
medicine) and Ms H Storey, V Langsbury, A Dwyer
and A Watts (secretarial).

The participating general practices were (name of
liason partner from each practice only): Dr A McPher-
son, Oxford; Dr A Markus, Thame; Dr D Leggett,
Oxford; Dr M Agass, Berinsfield; Dr D Otterburn,
Abingdon; Dr S Street, Kidlington; Dr V Drury,
Wantage; Dr R Pinches, Abingdon; Dr N Crossley,
Abingdon; Dr H O'Donnell, Deddington.

The study nurses were Mrs S Price, Mrs E Mogridge
and Mrs C Clifford.
