SUMMARY The presence of phytanic acid in tissues and plasma has been considered diagnostic of heredopathia atactica polyneuritiformis (Refsum’s disease), but recently slightly raised plasma phytanic acid levels have been reported in other conditions. Forty two people were found to have a phytanic acid level of 0–33 μmol/l. Fourteen patients with heredopathia atactica polyneuritiformis had a plasma phytanic acid level before treatment of 992–6400 μmol/l. Five patients with retinitis pigmentosa but not heredopathia atactica polyneuritiformis had plasma levels of 38–192 μmol/l. It was concluded that some patients with retinitis pigmentosa without heredopathia atactica polyneuritiformis but a raised plasma phytanic acid may represent a group of patients with a disease or diseases as yet uncharacterised apart from the retinal condition.

Phytanic acid (3, 7, 11, 15 tetramethylhexadecanoic acid) is a normal constituent of food and is found particularly in the fat of ruminant animals and in dairy products. Unlike other naturally occurring fatty acids, phytanic acid cannot be metabolised by beta-oxidation because the methyl side chains block the enzymatic action; an initial alpha-oxidation is necessary for its catabolism. As a result of a specific defect in alpha-oxidation in patients with heredopathia atactica polyneuritiformis (HAP) (Refsum’s disease), phytanic acid accumulates in large amounts in their tissues and plasma. The disease is characterised by retinitis pigmentosa, ataxia and polyneuropathy and in addition there may be anosmia, sensorineural hearing loss, ichthyosis and cardiac abnormalities. At the time of diagnosis patients with HAP usually have plasma phytanic acid levels above 800 μmol/l while normal people have been considered to have undetectable levels.

Recently abnormalities in the fatty acids including moderately raised phytanic acid levels have been reported in several childhood conditions including Zellweger’s syndrome, adrenoleukodystrophy, infantile Refsum’s syndrome and piperolic acidaemia. A plasma phytanic acid level as high as 320 μmol/l was found in one case of adrenoleukodystrophy. The plasma levels of other fatty acids are also abnormal in these conditions. In some of these children there is a more general abnormality in the number of peroxisomes in the skin fibroblasts and therefore this group of conditions, in none of which is the biochemical abnormality confined to a defect of phytanic acid metabolism, has been termed the peroxisomal disorders.

The significance of plasma phytanic acid levels in adults is uncertain. Although very high levels of plasma phytanic acid are diagnostic of HAP, the interpretation of lower levels is more difficult. The level of phytanic acid in the plasma of patients with HAP varies considerably as it rises when the disease worsens and may fall to very low levels with treatment. Low levels of phytanic acid have been detected in relatives of patients with HAP.

Methods

Forty two hospital inpatients were studied: 37 preoperative orthopaedic patients and five general medicine patients. Their consent was obtained and venous blood taken on two occasions; first in the afternoon as a random non-fasting sample and the second in the morning after at least an 8 hour fast. Information about age, sex, medication, major illnesses and smoking habits was obtained. None suffered from HAP. The blood was analysed for fasting lipids and fasting and non-fasting plasma phytanic acid. The presenting plasma phytanic acid levels of the 14 patients with HAP who have attended Westminster Hospital are given for comparison. A group of patients with neurological or ophthalmic abnormalities who had previously been identified because of slightly raised phytanic acid was reviewed.

Cholesterol, triglyceride and high density lipoprotein were
estimated using routine laboratory methods (Technicon autoanalyzer 11). Plasma phytanic acid was estimated by gas-liquid chromatography (GLC) analysis of the methyl esters as previously described with the modification that instead of a 1·5 m glass column packed with 10% polyethylene glycol adipate (PEGA), a 12 metre BP10 fused silica column (internal diameter 0·25 mm, using an oven temperature of 170°C and carrier gas inlet pressure of 41 kPa Hydrogen), obtained from Scientific Glass Engineering was used. The modification made no difference to the numerical results but improved the separation from other fatty acids. The log retention value of methyl ester of phytanic acid relative to methyl pentadecanoic acid under these conditions was 0·473 (SD 0·002). The limit of detection of phytanic acid was 3·2 μmol/l.

Results

Normal Controls. Of the 42 patients, 15 were male and 27 female, eight were aged between 16 and 30 years, 14 between 30 and 60 and 20 were over 60 years. Five patients had abnormal lipid profiles. The plasma phytanic acid levels ranged from zero (that is, less than 3·2 μmol/l) to 33 μmol/l although most samples contained less than 22 μmol/l. The distribution is shown in figs 1 and 2. Undetectable levels occurred in both fasting and non-fasting subjects but not always in the same person.

The means for the fasting and non-fasting levels in these normal persons were 7·7 μmol/l and 8·3 μmol/l. Because of the large number of results at unrecordable levels a normal distribution was not obtained and a standard deviation would be unhelpful. The normal level would be better expressed as saying the 95th percentile lies below 22 μmol/l for fasting and 24 μmol/l for non-fasting subjects. There was no difference shown between males and females, between younger and older adults or between those with normal and abnormal lipid profiles.

The initial plasma phytanic acid level in the 14 patients with HAP seen at Westminster Hospital prior to the commencement of dietary treatment ranged between 992 and 6400 μmol/l (mean 2151 μmol/l). After treatment the levels fell in all patients to between 16 and 1060 μmol/l (mean of 310 μmol/l). The plasma phytanic acid levels of the group of adult patients on a normal diet with slightly raised phytanic acid levels, retinitis pigmentosa and other neurological disorders, but not HAP are given in table 1. The levels ranged from 38 to 192 μmol/l.

The significance of plasma phytanic acid levels in adults

Discussion

The presence of trace amounts of phytanic acid in a normal population has been reported previously but the normal range has never been defined. Avigan measured the phytanic acid in a pooled sample of sera from 200 non-fasting healthy male blood donors and obtained a value of 6.4 μmol/l for phytanic acid, a figure which is close to the average found in this study. In the three individual samples measured the level was 1.3 to 6.4 μmol/l. Kremer reported the phytanic acid levels to vary between 0.2 and 0.6% of total lipids which is a test not directly comparable, as the total lipid levels were not stated. Two other workers have separately attempted to measure phytanic acid levels in controls. Try found the phytanic acid not raised in the plasma of 73 patients who had retinitis pigmentosa or a neurological disorder, but the limit of detection of the assay was only 64 μmol/l and Poulos found all 50 of his controls to have less than 16 μmol/l which was the limit of detection of his assay.

The method of assay used in the present study is similar to previous methods, but a different column was used. Previously the use of traditional polar and non-polar packed columns such as PEGA and APL ('Apiezon-L') for the analysis of phytanic acid caused problems because on PEGA phytanic acid coelutes with margaric acid and on APL with unsaturated 18 carbon fatty acids such as oleic acid. The capillary column used in the present study is only slightly polar and separates phytanic acid from all other fatty acids and thus ensures an accurate analysis. The shape of the peaks obtained with the capillary column is such that automatic integrators are less likely to miscalculate the areas.

This study has shown that:

1. Using sensitive techniques phytanic acid can be measured in small amounts in the plasma of some normal people.
2. Phytanic acid levels can vary in the same normal individual being undetectable at some times and measurable at others.
3. There is no significant difference between 8 hour fasting and non-fasting levels of phytanic acid in the normal person.
4. Age, sex and abnormal lipid profiles do not affect phytanic acid levels in the normal population.
5. Phytanic acid levels in 95% of normal individuals are less than 22 μmol/l and any level above 33 μmol/l should be considered abnormal.

Five patients who have retinitis pigmentosa and some but not all the features of HAP had plasma phytanic acid levels above, but not greatly above, the maximum normal level of 33 μmol/l. A markedly raised phytanic acid is not a feature of patients with retinitis pigmentosa unless they also have HAP (see table 2). However none of these five patients had a plasma level sufficiently elevated to be comparable with the initial plasma phytanic acid levels of the 14 patients with HAP. These five patients may be suffering from a syndrome independent of HAP, which is associated with a mild rise in the phytanic acid level in the blood.

Using the techniques described in this paper and having defined a normal limit for the plasma phytanic acid it should now be possible to distinguish a group of adults who are not relatives of patients with HAP and therefore possible carriers of a gene for HAP but who have unelucidated conditions which are not infantile peroxisomal disorders but which cause slight elevation of phytanic acid levels. In summary, for patients with recognised syndromes the plasma phytanic acids which may occur are given in table 2. The five patients in table 1 would not conform to one of the recognised groups and could represent a separate entity.

We thank the Retinitis Pigmentosa Society for a Research grant in aid of this work.
