PET: its clinical role in neurology

Positron emission tomography (PET) provides a non-invasive means of measuring the metabolism, perfusion, and pharmacology of human organs in vivo. A tracer tagged with a short-lived positron emitting isotope, such as $^{15}$O, $^{13}$C, or $^{18}$F (half-lives 2, 20, and 110 minutes respectively), is generated by a cyclotron and administered intravenously, or by inhalation to the subject. Quantitative tomographic images of regional cerebral function can be generated using established mathematical models from the scans of regional cerebral tracer uptake with a knowledge of the arterial plasma tracer activity. Examples of tracers in common usage to measure blood flow are $^{15}$O, $^{13}$O, and $^{18}$FDG, while oxygen and glucose utilisation can be assessed with $^{15}$O and $^{18}$F-2-fluoro-2-deoxyglucose (FDG) respectively.

Levels of striatal $^{18}$F-F-6-fluorodopa and $^{11}$C-nomifensine uptake provide a measure of functional integrity of the nigro-striatal dopaminergic system, while dopamine D$_2$, and D$_3$, serotonin 5HT$_2$, opiate, and benzodiazepine receptor densities can be estimated using tracers such as $^{11}$C-SCH 23390, $^{11}$C-Raclopride, $^{18}$F-Setoperone, $^{11}$C-Carfenetanil and $^{11}$C-Diprenorphine, and $^{11}$C-Flumazenil respectively. PET has been criticised as being highly expensive, relatively unavailable, and that it has contributed little to the clinical practice of neurology. The first two criticisms are becoming less valid as "Clinical PET" centres begin to spring up, and indeed there is now an Institute of Clinical PET in the USA. As for the third criticism it is perhaps worth remembering that PET was never originally envisaged as a clinical tool. Despite this, a number of interesting roles for PET in the practice of clinical neurology have emerged which this editorial will discuss.

a) The dementias
It is now established that the majority of patients with Alzheimer's disease show a characteristic pattern of reduced cortical metabolism and blood flow which is most severe in the posterior parietal and temporal lobes, with relative sparing of the sensorimotor and occipital cortices. These changes on functional imaging may be present before any atrophic changes are evident on CT or MRI. More interestingly, if patients complaining of recent onset of poor short term recall are scanned, there is a high correlation between the presence of posterior parietal and temporal hypofunction on PET and the subsequent development of frank dementia of Alzheimer type (DAT). Functional imaging can therefore provide a means of distinguishing memory impairment due to early DAT from that due to other causes such as the pseudo-dementia associated with depression. In depression, like DAT, a general reduction in cortical blood flow and metabolism occurs, but pre-frontal rather than parietal and temporal cortex is most severely involved, and the prefrontal hypofunction may reverse on successful treatment of the affective disorder.

At its onset dementia due to frontal lobar degeneration may be clinically difficult to differentiate from Alzheimer's disease as loss of short-term recall and change of personality are frequent presenting features of both conditions. Subjects with Pick's disease show generalised cortical hypometabolism on functional imaging, but in contrast to Alzheimer's disease the prefrontal rather than the posterior parietal and temporal regions are most severely affected. Prefrontal hypofunction is not specific for Pick's disease, but can also be found in dementia of frontal type (DFT) due to spongiform degeneration, and in the so called "sub-cortical dementias" due to conditions such as progressive supranuclear palsy (PSP) and Huntington's disease. While cortical glucose metabolism is most severely reduced in frontal regions in PSP, it has suggested that it is the premotor and supplementary motor areas rather than the prefrontal areas that are targeted, distinguishing this condition from Pick's disease. Demented patients with Parkinson's disease generally show a DAT rather than DFT pattern of cortical hypofunction. There have not been enough pathological studies yet to determine whether the low posterior parietal and temporal metabolism seen in demented PD patients simply represents coexistent Alzheimer's disease, or whether it can also result from cortical Lewy body disease or loss of cortical cholinergic, noradrenergic, and serotonergic afferents.

It can be seen therefore that PET can help to distinguish the cortical and subcortical dementias in their early clinical phases by delineating patterns of altered regional cerebral blood flow and metabolism, and so aid in counselling patients and their relatives, and in classifying dementia patients for entry into therapeutic trials. PET can also differentiate the degenerative dementias from other dementing illnesses such as multi-infarct disease where randomly distributed focal deficits in cortical and subcortical metabolism are found and from normal pressure hydrocephalus where cortical function is uniformly depressed. It will be necessary to perform prospective clinical trials, however, to fully evaluate the sensitivity and specificity of functional imaging in the differential diagnosis of the dementias.

An interesting sub-group is the focal cortical degenerations leading to progressive aphasia, apraxia, agnosia and...
cortical blindness. The pathologies of these conditions are not unique: focal Alzheimer, Pick's and spongiform changes have all been reported. These patients frequently have normal structural imaging at the disease onset, and have on occasion been thought hysterical. Functional imaging provides a sensitive means of demonstrating the presence and extent of the focal cortical hypometabolism present in these patients, and may show changes when structural imaging is unhelpful. A recently recognised entity is corticobasal degeneration, also known as cortico-dentatorigral degeneration and neuronal achromasia. This condition presents as an asymmetric, non-levodopa responsive, akinetic-rigid syndrome with apraxia or cortical sensory loss in affected limbs. An alien-limb (a limb that performs involuntary apparently purposeful movements), supranuclear gaze palsy, pseudobulbar palsy, and myoclonus may also be present. The pathology consists of asymmetrical foci of swollen achromatic neurons in the posterior frontal, inferior parietal, and superior temporal cortices, substantia nigra, and dentate nuclei. PET reveals a characteristic pattern of hypometabolism involving these cortical areas even when structural imaging is normal, and so can aid in diagnosing this fascinating condition.

PET can also be used to demonstrate the functional effects of pathology that remain occult to conventional clinical assessment. Hatazawa et al. measured regional cerebral glucose metabolism in motor neuron disease (MND). Eight of their MND cases had both lower and upper motor neuron involvement and all showed widespread cortical and sub-cortical hypofunction, the sensorimotor cortex being most severely affected. Four MND patients with only lower motor neuron involvement showed no abnormalities of cerebral function. The widespread cerebral hypofunction in the group of eight patients with upper motor neuron disease is probably caused by diffuse loss of Betz cells from the cortex and disconnection of structures from the primary motor cortex and pyramidal tracts. Functional imaging should potentially provide a sensitive means of determining whether upper motor neuron involvement is present in these MND patients where this is in doubt. PET studies have also shown that multiple sclerosis patients develop severe generalised cortical hypometabolism in association with their white matter disease, and that this is too extensive to be simply a consequence of cortical disconnection by the discrete white matter plaques present. It would appear that apparently structurally normal brain tissue functions abnormally in MS patients, explaining the high incidence of cognitive dysfunction in this condition.

b) Cerebrovascular disease

PET can be used to study the widespread metabolic derangements caused by discrete ischaemic lesions, to study the adaptive mechanisms the brain brings into play to effect a functional recovery from strokes, and to study the haemodynamic changes associated with the pre-ischaemic, and ischaemic state. As a lacunar infarct may cause extensive functional disconnection, PET is a more sensitive means of detecting ischaemic lesions than CT or MRI. The size of metabolic deficits, and the level of their glucose utilisation, has been shown to correlate with the eventual clinical outcome of stroke patients.

Ninety per cent of motor cortex pyramidal fibres project to the contralateral limbs, but a functional ipsilateral pathway exists as shown by the mild proximal weakness of ipsilateral limbs experienced by patients after stroke involving the motor cortex. If patients who have made an apparent complete clinical recovery from a hemiparesis are studied with PET, abnormalities of cerebral activation can be detected. Normally when the fingers of one hand are touched in turn with the thumb there is a significant increase in blood flow in the contralateral sensorimotor cortex, bilateral supplementary motor and premotor areas, and ipsilateral cerebellar hemisphere. Some patients who have recovered from hemipareses show abnormal ipsilateral sensorimotor cortex and contralateral cerebellar hemisphere activation when the affected hand is used, suggesting that activation of ipsilateral motor pathways plays a role in their functional recovery. Similarly, patients who are recovering from expressive dysphasia due to dominant hemisphere stroke may show abnormal activation of the non-dominant hemisphere if asked to generate words.

When a carotid artery becomes more than 70% stenosed, and cerebral perfusion pressure falls, two adaptive mechanisms come into play. Firstly the brain attempts to maintain blood flow by reducing vascular resistance. The result is dilatation of the distal microvasculature with an increase in cerebral blood volume in the territory supplied by that carotid artery. Secondly, as vasodilatation becomes maximal and blood flow falls, the brain maintains oxygen metabolism by increasing the fraction of oxygen extracted from the arterial supply from a normal 40% level towards a maximal 100%, at which point a state of ischaemia is reached. Any further fall in perfusion pressure will result in infarction. Acute stroke is associated with raised levels of arterial oxygen extraction, low blood flow, and acid tissue pH. As infarction is completed the cerebral oxygen extraction and metabolism fall to low levels. Reperfusion may occur within the next few hours leading to a rise in blood flow and conversion of tissue pH from acid to alkaline. As tissue metabolism remains low, however, restoration of cerebral perfusion results in a state of luxury perfusion.

All the above regional cerebral haemodynamic and metabolic changes can be monitored with PET, and patients with impaired haemodynamic and oxygen reserves due to stenosed or occluded extra–cranial arteries can be identified. It is now well established that revascularisation surgery can reverse the haemodynamic effects of carotid stenosis. Only small numbers of patients have been studied to date, however, and reported clinical follow up is limited to two years. Data from a single uncontrolled, non-blinded study are discouraging, failing to show any marked improvement in prognosis of patients with dilated microvascularulation who had revascularisation compared with those who were treated conservatively.

Controlled trials are needed to resolve this question. PET has shown that many infarcts spontaneously reperfuse within hours of the onset. Consequently the use of therapy designed to increase cerebral perfusion from this time onwards, such as haemodilution and calcium channel antagonists, is inappropriate. If attempts are going to be made to revascularise ischaemic brain then PET findings suggest that this must be done within those first hours while oxygen extraction remains high. With the advent of cerebral protective agents, such as glutamate antagonists and free radical scavengers, a valuable future role for PET is likely to lie in the evaluation of the efficacy of these drugs in restoring cerebral metabolism after infarction.

c) Movement disorders

PET can provide a valuable adjunct to clinical assessment in helping to distinguish the various akinetic-rigid syndromes, and is able to detect sub–clinical involvement in at-risk subjects. The patterns of cortical metabolic disturbance associated with akinetic rigid syndromes have already been discussed in section a. Striatal metabolism is
normal in Parkinson's disease (PD), while conditions associated with striatal degeneration such as multiple system atrophy (MSA) and progressive supranuclear palsy (PSP), show significant falls in striatal glucose utilisation. Huntington's disease results in severe degeneration of the caudate nuclei, and affected patients may show low caudate glucose metabolism before any atrophic changes are evident on CT. Unfortunately, the finding of selective caudate hypometabolism is not specific for HD, having also been reported in chorea associated with benign familial chorea, neuroacanthocytosis, and dentatopallidolubulysian atrophy. Subjects at risk for Huntington's disease have been studied with PET, and a high concordance rate of PET positive caudate hypometabolism and DNA linkage abnormalities has been reported. It is unlikely that functional imaging will replace DNA studies as a means of diagnosing HD, but where inadequate genetic material is available it may prove useful in supporting or refuting the diagnosis.

The pre- and post-synaptic dopaminergic system has been extensively studied with PET in patients with movement disorders. In sporadic levodopa responsive PD there is a characteristic pattern of striatal \(^{18}\)F-Dopa uptake, putamen tracer uptake being on average reduced to 40%, and caudate 80%, of normal. Striatal \(^{18}\)F-Dopa uptake reflects functional integrity of the nigro-striatal dopaminergic projections, and these PET findings fit in with the pathological observation that nigra compacta cell counts are reduced to 15–30% of normal in PD, the ventro-lateral projections to the putamen being most severely affected. Levels of putamen \(^{18}\)F-Dopa uptake correlate with locomotor function of PD patients, and on-off fluctuators have lower levels of tracer uptake than patients with a sustained response to therapy. PSP patients also show a severe fall in putamen \(^{18}\)F-Dopa uptake, but in contrast to PD the caudate tracer uptake in PSP is as severely affected as putamen. Again these PET observations fit with the pathological finding of a uniform nigral involvement in PSP.

\(^{18}\)F-Dopa PET can be used to detect presymptomatic nigral involvement in subjects. Abnormal striatal \(^{18}\)F-Dopa uptake has been demonstrated in asymptomatic subjects exposed to MPTP, and occasionally in patients made rigid with conventional doses of dopamine receptor blocking agents used as vestibular sedatives or neuroleptics. Work is currently under way scanning twins and relatives of Parkinson's disease patients with \(^{18}\)F-Dopa to try and determine the role of inheritance in this condition. Preliminary data suggest that the concordance for nigral pathology in PD twin pairs may be higher than was previously thought. Patients with isolated tremor are also having \(^{18}\)F-Dopa PET to clarify the relationship between essential tremor (ET) and nigral pathology. Our data currently suggest that patients with a predominantly postural tremor and a verifiable family history of ET have normal levels of striatal \(^{18}\)F-Dopa uptake (Brooks DJ, unpublished observations).

The beneficial effects of dopamine agonists in PD are mediated through dopamine D\(_2\) receptors. There has been confusion in the pathological literature over the status of striatal dopamine D\(_2\) receptors in Parkinson's disease, up and down regulation, and normal levels have all been reported. Using the D\(_2\) antagonist \(^{125}\)I-Raclopride, two PET studies have now shown that in untreated PD there is relative upregulation of putamen D\(_2\) binding sites contralateral to the more affected limbs. Absolute levels of striatal D\(_2\) binding sites in untreated PD fall within the normal range, while in chronically treated PD subjects, who have developed a fluctuating response to levodopa, caudate and putamen D\(_2\) binding sites are uniformly reduced. Poor levodopa responsive MSA and PSP patients show similar reductions in striatal D\(_2\) binding site density to on-off PD fluctuators, though putamen is targeted in MSA and caudate in PSP. This suggests that the lack of levodopa response in MSA and PSP is not due to loss of striatal D\(_2\) sites alone, but is caused by loss of other basal ganglia and brain stem connections.

PET has also been used to study the cerebellar ataxias. In sporadic and familial olivopontocerebellar atrophy (OPCA) cerebellar and brain-stem glucose hypometabolism are found before CT or MRI abnormalities are seen. PET can also be used to demonstrate cerebellar involvement in patients with multiple system atrophy.

Interestingly, PET has also been used to clarify the site of cerebellar degeneration, patients with early Friedreich's ataxia show elevated rather than reduced cerebellar glucose metabolism, though this later falls as the disease becomes more advanced.

In summary, it can be seen that PET can be used to help distinguish the various degenerative causes of akinetic-rigid syndromes by revealing their different patterns of cortical, striatal, and cerebellar metabolic dysfunction, and their different patterns of disruption of the pre- and post-synaptic striatal dopaminergic systems. These changes on functional imaging are often seen in the absence of abnormalities on CT or MRI. PET can also be used to detect the presence of underlying nigral pathology in patients with isolated tremors or drug-associated rigidity, and striatal hypofunction in subjects at risk for Huntington's disease.

d) Epilepsy

The majority of functional imaging studies have been performed on patients with focal epilepsy. A problem with the use of PET for studying the regional cerebral metabolic or blood flow changes associated with seizures is that PET tracers have short half-lives. As a consequence unless a patient has a spontaneous or induced fit during scanning, most PET studies are of necessity interictal. The most widely used PET metabolic tracer has been \(^{18}\)FDG, whose cerebral uptake reflects glucose metabolism. This tracer is poorly extracted by the brain and so tracer uptake must be followed for 45 minutes. If a subject has a seizure during an FDG scan, the effect of the seizure on tracer uptake is dependent on the proximity of the fit to the time of tracer injection.

Despite these methodological problems a considerable amount of PET FDG data on epileptic subjects has been gathered. Generalised seizures appear to cause a diffuse increase in cerebral glucose utilisation, but the FDG approach does not have the temporal resolution to determine the site of initiation of ictal activity. Sixty to eighty per cent of patients with lateralised foci on surface and depth EEG show ipsilateral glucose hypometabolism interictally, the area of low FDG uptake being far more extensive than that of the ictal EEG. Those patients with partial focal seizures that have had ictal scans show glucose hypermetabolism in the same area as the interictal glucose hypometabolism, though changes may be more widespread due to the spread of seizure activity. Seizure lateralisation determined by ictal PET studies has a 90% concordance with that determined by surface and depth EEG. Pathological studies on resected temporal lobe found lesions with a 60–80% concordance with PET lateralisation of seizure foci. PET is most frequently abnormal in cases of mesial temporal sclerosis, but will also detect neoplasms, vascular malformations, and heterotopias responsible for focal seizures.

Initial series suggested that MRI was a far less effective technique for detecting abnormalities in focal epilepsy than functional imaging, picking up lesions in only 40% of
cases. With the advent of new scanning sequences, and cuts orientated along the axis of the temporal lobes, MRI is now more sensitive at detecting mesial temporal sclerosis and may be becoming as effective as PET in lateralising focal abnormalities. While functional imaging provides an excellent means of lateralising focal seizures, the metabolic disturbance revealed is often widespread and so PET may not readily differentiate frontal from temporal lobe foci. In spite of this drawback, several neurosurgical centres now feel that depth electrode ECoG studies are no longer necessary to lateralise the focus in patients with a good history for focal epilepsy, but a normal surface EEG, if regional hypofunction can be demonstrated with interictal functional imaging.

e) Conclusions

PET can demonstrate characteristic patterns of disruption of regional cerebral hypometabolism and neurotransmitter systems associated with the cortical and sub-cortical degenerations, and so help to characterise the type of dementia or akinetic-rigid syndrome affecting patients when this remains unclear after clinical assessment and structural imaging. Sub-clinical involvement in subjects at risk for degenerative dementia, such as Parkinson's disease and Huntington's disease can also be demonstrated. In cases where extracranial artery stenosis is causing impaired cerebral perfusion, PET can assess the degree of haemodynamic compromise present, and provide a rationale for revascularisation. Functional imaging is valuable for lateralising epileptic foci in patients with focal seizures who have a normal surface EEG and are under consideration for temporal lobectomy, enabling avoidance of the use of depth electrode studies in certain instances. Finally PET can give insight into the adaptive mechanisms the brain uses to overcome focal injury, and can directly monitor the effects of therapy on regional cerebral metabolism.

Some of the applications of PET described in this editorial can also be studied with the cheaper and more widely available technique of single photon emission computerised tomography (SPECT). Using $^{99m}$Tc tracers such as HMPAO, SPECT provides qualitative measurements of regional cerebral blood flow, and tracers are now available for studying $^{13}$N choline, and benzodiazepine receptors. Using SPECT Alzheimer's disease can be distinguished from DFT, the functional effects of focal degenerative disease and infarction can be detected, and the flow changes associated with focal epilepsy can be lateralised. It is not the purpose of this editorial to compare PET and SPECT, but rather to illustrate their clinical role in neurology. Currently PET is the more versatile and sensitive of the two techniques, but as the designers of SPECT tracers become more innovative the gap between PET and SPECT is likely to close.

DAVID J BROOKS

MRC Cyclotron Unit, Hammersmith Hospital, London.

Hippocrates 460–377 BC

Hippocrates recognised diseases of the brain. He noted that the brain had two halves and was well supplied with blood vessels, some slender but two were stout. Hippocrates believed that these vessels contained air. Indeed, at that time, nerves were not distinguished from tendons or ligaments. The brain, however, was associated with intelligence, dreams, thoughts and epilepsy. It was assumed to have a cooling mechanism mediated by secretion of phlegm or, as it was also called, pituita.

At the time of Hippocrates it was known that a head wound could be followed by paralysis of the opposite side of the body, whilst spinal cord compression could cause anaesthesia and weakness as well as urinary and faecal retention. Hippocrates described peuperal hemiplegia, aphasia, migraine, irregular respiration from cerebral disease, febrile delirium, mania and melancholia. He also knew of the neurological sequelae of alcoholism and noted that “Unaccustomed attacks of anaesthesia and numbness are impending signs of apoplexy”.

Hippocrates has been featured on stamps on a number of occasions. The illustrations here commemorate the reincorporation of the Dodecanese Islands into Greece. On the right is the plane tree at the centre of the town of Cos in the shade of which Hippocrates is reputed to have taught his pupils.

These stamps, the first in a series to be published in this journal, can be found in the catalogues of Stanley Gibbons (670 and 817) or Scott (514 and 657).
