Matters arising

Facco replies:

Some of the criticisms on which I agree with Dr Lang do not appear relevant. Conversely, some of the remarks appear to misunderstand our work. I shall try to answer concisely all Dr Lang's comments:

a) I did not feel so optimistic as I only suggested adding auditory brain stem responses (ABR) and somatosensory evoked potentials (SEP) to the clinical evaluation of brain stem death. The absence of undue optimism is emphasised by the question mark in the title.

b) I agree that our data are not completely new; nevertheless, in most studies dealing with coma and/or brain death, SEP's are recorded using a frontal reference. This does not allow a clear definition of far field components (namely, P13, 14 and N13) and therefore precludes any evaluation about conduction through the brain stem in patients with absent N20. Our study emphasises the need for the non cephalic reference, when a conduction block at the cervico-medullary junction or in the lower brain stem is to be checked (absence of components following P13 or dissociation N13/P13). In my opinion this is the only right method for SEP recording in brain death. We have already reported elsewhere1 on the possible reversibility of N20 loss, but so far we have not found a reversible disappearance of the P13-N18 complex.

c) I think that the analysis of consecutive cases may be useful to check the ratio of sectors unrelated to brain death which might affect the evoked potentials, rather than check their reliability. As properly used: all investigations and clinical signs have their own limits and pitfalls, not only ABR and SEP, and the main concern in clinical practice is to use them properly.

d) The statement that "the EEG is far from being relevant" is not a conclusion based on our results, a detailed account of EEG limits and pitfalls is not necessary, as Pallis in 1983 has already published an exhaustive analysis.

e) We recommended the use of evoked potentials, but did not advocate their use instead of the EEG: their use does not prevent the recording of the EEG as well, if thought appropriate.

f) I agree that the relevance of the EEG partly depends upon the very concept of brain death (that is, brain stem death or death of the whole brain), as emphasised by Dr Lang. However, brain stem death must also be fulfilled, whatever the accepted concept of brain death. When the death of the whole brain is to be checked, the EEG and/or cerebral blood flow may be helpful confirmatory tests to be added to diagnostic criteria.

g) I did not mention the EEG in results as it was not strictly relevant to the brain stem. In Italy the EEG is mandatory as quoted in our introduction; as a result our patients must have a flat EEG to be declared brain dead.

h) The ABR was able to confirm brain stem death in more than 11% of cases. It is a 22% who showed a preserved wave I and in four further cases (11%) in whom the disappearance of all waves was checked by serial monitoring. Therefore, a total of 33% of confirmations was present in this series by ABR.

i) So far we have not found that muscle activity caused problems of interpretation; there is only one case reported by Guerit.1

j) Finally, according to the last sentence of Dr Lang and his quotation1 I already pointed out the perfect agreement between evoked potentials data and the UK criteria of brain death in our series: that means that a careful clinical diagnosis is reasonably safe even without confirmatory tests. However the concept of brain stem death implies the diagnosis of the death of the whole brainstem, rather than a part of it; consequently, I believe that we need to check all the brainstem anatomic structure and this is what we routinely do in our patients. There is no reason to avoid the "objective" assessment of easily and non invasively explorable pathways, such as the auditory and somatosensory ones. Our results enabled us to recommend ABR and SEP for the sake of coherence with the underlying concept of brain stem death and for the sake of safety (which implies both an "objective" confirmation and the exclusion of false positives).

Transient entrapment neuropathy of the posterior interosseous nerve in violin players

I was most interested to read the article by Drs Maffulli1 describing what they consider to be transient entrapment of the posterior interosseous nerve in violin players, and I am grateful to them for quoting several of our publications. However, I have some problems with this report.

The diagnosis of this painful form of posterior interosseous neuropathy, often referred to in the medical literature as the radial tunnel syndrome, is a difficult one since, as in the cases described here, no neurological deficits are detectable. The occurrence of pain is followed by repetitive activities of positions, even when it appears to be in the distribution of a single nerve and even when there appears to be tenderness at some point along the course of that nerve, rarely provides convincing evidence of nerve entrapment. The authors do describe transient "muscular deficit" in specific muscles supplied by the radial nerve, although these patients alleged had weakness of the extensor carpi radialis brevis, which is supplied by a branch of the radial nerve proximal to the posterior interosseous nerve.

I am particularly puzzled by the repeated description provided by the authors that prolonged pronation of the forearm while playing the violin seemed to predispose to this condition. It is easy to identify a single cause, except for the rare individual who plays "left-handed," is held in a position of extreme supination, not pronation, while playing.

Posterior interosseous neuropathy is not only rarely identified in musicians. A case of the paralytic form was described by Guillian and Courtellemont2 in an orchestral conductor. One of the patients described by Woltman3 had not reached the age of 13 before right hand weakness. Charness et al described a flautist with a left posterior interosseous neuropathy.

Over 500 instrumentalists evaluated over the past 12 years, I have seen a flautist and a percussionist with alleged posterior interosseous neuropathy. Both were seen post operatively and had minimal clinical and electrodiagnostic evidence of partial radial neuropathy at that time. I have studied 175 violinists and viola players, including 106 who had exclusively or predominantly left upper extremity symptoms, and I have not been able to identify a single case of posterior interosseous neuropathy although nerve entrapment has been assiduously looked for both clinically and electrodiagnostically.

About 25% of these patients had an entrapment of some sort; most of the remainder had a form of muscle-tendon overuse.4 Thus I am surprised to learn that Drs Maffulli have been able to find 11 such cases in under four years. The problem with proposed diagnosis of this painful but non-paralytic form of posterior interosseous neuropathy is that the temptation to offer surgical correction becomes irresistible, sometimes prematurely. This is reminiscent of the situation in median neuropathy associated with thoracic outlet syndrome, a diagnosis which has received considerably more attention than the radial tunnel syndrome. I believe that both exist but we must strive to define both disorders more rigorously so that we can provide the most appropriate therapy.
