We have examined clinically, three other patients with clear dystonic head tremor in whose head tremor was altered by the position of the head in the anterior-posterior plane. In none of the others could we demonstrate a vestibular (otolith) mechanism. Despite these negative observations for a clear otolith influence upon head tremor electrophysiological measurements have shown that otolith spinal reflexes may be modulated by both head and body position. Thus there still remains the possibility that a change in head or body position may itself in modify vestibular influences upon body movement.

Probable cases of Mast syndrome in a non-Amish family

Complicated forms of hereditary spastic paraplegia are rare. A 58 year old Polish woman was admitted with a clinical picture of slowly progressive spastic paraplegia, dysarthria, presenile dementia and mild athetosis.

At the age of 16 her gait became shuffling. Before the age of 30 she used a walking stick, since the age of 35 she has needed a walking frame and from the age of 40 she has become wheelchair bound. During the 45th year, urinary incontinence began. On admission, aged 48, significant bradyphrenia and comprehension difficulties were noted and during the following years she presented a further mental deterioration. She is now bedridden and her speech restricted to rare, usually inappropriate single syllable aphasia, which are sometimes repeated. She has difficulty swallowing fluids. She often shows spontaneous repeated slow turning of the head to the right and left and mild tortuous movements of the shoulders. Except for a divergent strabismus there are neither oculo-motor abnormalities, nor fundoscopic anomalies. There is a slight bilateral facial weakness. The fine motor hand skills are lost without clear paresis of the upper limbs. The strength of leg muscles measures about 1 to 2/5. There were neither sensory deficits nor cerebellar signs. Deep tendon reflexes in the upper limbs were increased slightly. Knee jerks were unusually brisk and without clonus; ankle jerks were absent. Plantar responses were extensor. Snout reflex and bilateral palommental reflexes were present whilst corneomandibular reflexes were absent.

The following laboratory investigations showed no significant abnormalities: routine blood examination (except for intermittent elevation of glucose with normal haemoglobin A1c), creatinin, ketone, copper, lipids, very long chain fatty acids ratios C24/C22 and C26/C22, vitamin E, vitamin B12, folate, cortisol, adrenocorticotropic hormone, thyroid hormones, arylsulfatase A and hexosaminidase A + B. The CSF protein was 590 mg/l with normal electrophoretic pattern.

The EEG showed mild general slowing. Nerve conduction studies and needle electromyography showed a mild axonal polyneuropathy. The somatosensory evoked potentials demonstrated a slightly prolonged central conduction time. An electrocardiogram was normal. MRI of the brain showed diffuse cortico-subcortical atrophy, periventricular hyperintensities, thin corpus callosum and less marked atrophy of the brainstem and cerebellum. Light microscopic and electron microscopic examination of conjunctiva and skin showed some membranous cytoplasmic body-like inclusions (Professor J J Martin, Dr C Ceuterick-de Groote, University Hospital Antwerp).

The family history revealed two similar cases (figure). There was no known consanguinity.

The monozygotic twin has an almost identical medical history and clinical picture. She is able to stammer a few simple words. Her answers are sometimes slightly more appropriate, particularly for old memories. Her knee jerks and ankle jerks are both unusually brisk, and the plantar responses are extensor. One brother died at the age of 53. The medical records and relatives described difficulties with walking from the age of 20 (maybe earlier). During the following decades he presented a progressive spastic paraparesis, dysarthria, mental deterioration and urinary and faecal incontinence; no deficits of sensation or coordination were demonstrated. There was dysphagia in his last years. Death was due to pneumonia.

The pedigree suggests an autosomal recessive inheritance. The neurodegenerative syndrome in this family seems fully comparable to the Mast syndrome, described in 1967 in an Ohio Amish family by Cross and McKusick. The gene appears to have been lost and recently reappeared in a large Amish community.

Ultrasonic TSH assay and anti-Parkinsonian treatment with levodopa

We have recently reported the association of Parkinson's disease and hyperthyroidism in a group of 10 patients. In that report, symptoms of Parkinson’s disease were always significantly exacerbated by the development of hyperthyroidism and improved by its successful treatment. We proposed that hyperthyroidism should be suspected in all Parkinsonian patients when their condition deteriorates. Since clinical diagnosis of thyrotoxicosis is difficult in Parkinsonian patients, they should have a comprehensive thyroid examination and, if there is the slightest suspicion of hyperthyroidism, a hormonal evaluation of thyroid function (free T3, T4, TSH).

Hyperthyroidism levels (T3, T4) have been found to be normal in Parkinsonian patients untreated or treated with levodopa. However, a decreased response of thyrotropin (TSH) after stimulation by TRH (thyrotropin releasing hormone) has been reported in Parkinsonian patients treated with levodopa. Such a decreased TSH response after TRH stimulation is observed during hyperthyroidism, and is sometimes the only hormonal abnormality, especially in elderly patients with autonomous thyroid nodules. Thus the decreased TSH response after TRH stimulation in patients treated with levodopa could be responsible for a false diagnosis of hyperthyroidism. These results, however, were obtained before the ultrasonic TSH determination with a monoclonal antibody assay was available. A low ultrasonic TSH level has the same significance as a decreased TSH response to TRH, indicating an increased negative feed-
back of thyroid hormones on pituitary TSH secretion. Thus basal ultrasensitive TSH level has become an important tool to detect hyperthyroidism, replacing the TRH-stimulation test.

The aim of our study was to determine whether chronic treatment with levodopa was able to lower the basal TSH levels, measured by an ultrasensitive assay, in Parkinsonian patients and thus be responsible for a false diagnosis of hyperthyroidism in such patients.

Thirty two Parkinsonian patients, mean (SD) age 73-12 (SD range: 30–88 treated with levodopa (187.5 mg/day to 700 mg/day) were included in the last month of the study. These patients were clinically euthyroid, had a normal thyroid examination and normal levels of free T₄. Blood samples were drawn at 8:00 am in fasting patients, from 8 to 12 hours after the last dose of levodopa or dopamine (free T₃ and free T₄). These patients were not receiving any other drugs known to modify thyroid function. Thirty age matched controls, also with similar levodopa doses, were studied, for comparison [mean (SD) 76-05 (9-31) years; range: 53–91]. Each patient and each control had titres of antithyroglobulin and antimicrosomal antibodies less than 1/320 and 1/800 respectively (haemagglutination assay). Free T₃ and free T₄ were measured using radioimmunoassay (RIA Amersham). Ultrasonic TSH was measured by radioimmunoassay, using a monoclonal antibody (RIA Behring). The sensitivity of this TSH assay is 0.02 mIU/l, the intra-assay and interassay coefficient of variations are 3.5% and 5% respectively. Comparisons of means were made with Student’s unpaired t test after verification of a normal distribution for the data.

Free T₃ [mean (SD) 3.8 (1.29) pMol/l; range: 1.3–5.7] and free T₄ [mean (SD) 13.4 (3.24) pMol/l; range: 8.5–21] levels were not significantly different in Parkinsonian patients treated with levodopa than controls (table). The ultrasonic TSH level was not significantly different in levodopa treated Parkinsonian patients [mean (SD) 1:71 (1.05) mU/l; range: 0:51–4] from controls [mean (SD) 1:45 (1.02) mU/l; range: 0.44–87 (table)]. Among the 32 patients, none had an ultrasonic TSH level below the normal range. Ultrasonic TSH level was not shown to be influenced by levodopa doses since no difference was noted between patients treated with less than 200 mg/day (n = 17) and those treated with more than 200 mg/day (n = 15) [1.64 (0.64) vs 1.97 (1.17) mU/l; not significant]. Furthermore, duration of levodopa therapy did not appear to modify ultrasonic TSH level since no difference was observed between patients treated for less than 12 months (n = 12) and those treated for more than 12 months (n = 20) [1.53 (1.20) vs 1.82 (1.08) mU/l; not significant].

Clinical diagnosis of hyperthyroidism is often difficult in patients with Parkinson’s disease because symptoms such as tremor, weight loss and sweating are common to both diseases, because thyrotoxicosis only produces few symptoms in elderly patients, and because Parkinson’s syndrome’s symptoms are in most cases. Thymus thyroid evaluation of thyroid function appears to be very helpful, for diagnosis of hyperthyroidism, in Parkinsonian patients. Ultrasonic TSH assay was a great improvement in hormonal thyroid function evaluation, leading to easier detection of hyperthyroidism. A low ultrasonic TSH level, with normal thyroid hormone, is frequently seen in elderly patients with autonomous thyroid nodules. Such patients require a thyroid scintigraphy to detect hyperfunctioning nodules, allowing the diagnosis of hyperthyroidism. Before the ultrasonic TSH assay was available, an absence of TSH response after TRH stimulation was the only method of detecting such hyperthyroid patients. As a decreased response of TSH after TRH had been reported in Parkinsonian patients treated with levodopa, it remains to be determined whether basal TSH levels, measured by ultrasonic assay were modified by levodopa treatment. In our study, basal TSH levels, measured by an ultrasonic assay, in Parkinsonian patients treated with levodopa, were not found to be lower than in age matched controls. No patient treated with levodopa had an ultrasonic TSH level below the normal range. Furthermore, in patients treated with levodopa, ultrasonic TSH level was influenced neither by the levodopa dose nor by the duration of levodopa treatment. In conclusion, Parkinson’s disease is not responsible for a false thyrotoxicosis in patients treated with levodopa, as in the general population.

Vestibular and ventilatory dysfunction in sensory and autonomic neuropathy associated with primary Sjögren’s syndrome.

Subacute sensory neuropathy was described by Denny-Brown in association with carcinomatous and has recently been described in elderly. In both primary Sjögren’s syndrome (SS). The primary pathology is in the dorsal root ganglia and consists of lymphocytic infiltration and neuronal cell destruction. We describe a patient with both sensory and autonomic neuropathy and the previously undescribed clinical features of vestibular and ventilatory dysfunction.

A 38 year old man presented with difficulty walking for one month. He had complained of pain and tingling in the feet and hands, patchy areas of abnormal sensation on the trunk and perioral paraesthesiae. He had experienced giddiness and dryness of the eyes and dry mouth for 6 months. There was severe impairment of proprioception and to and including the toes. The deep tendon reflexes were absent. In the upper limbs there was reduction of pinprick and light touch sensation in a distal distribution and loss of vibration sense and proprioception for the lower limbs. There was severe impairment of proprioception and to and including the knees. Romberg’s sign was positive and the gait was severely atactic. There was bilateral punctate keratitis in the interpalpebral distribution and the Schirmer’s test was 14 mm on the right and 4 mm on the left (normal > 5). On later examination, the Schirmer’s test revealed no laminae from either eye.

Significant results of investigations were that the RA latex test was negative, anticyclic cardiolipin antibody level was 8 (normal < 20) and smooth muscle antibody titre was 1:40. Screening for other collagen vascular diseases, including extractable nuclear antigens, were negative. CSF protein was initially 660 mg/l (normal < 400), CSF IgG was 55 mg/l (normal 10–60) and CSF IgG albumin was 0.14 (normal < 0.11). On a later occasion the CSF protein level was 1,100 mg/l. CSF electrophoresis did not reveal oligoclonal bands. Motor nerve conduction velocity was normal but sensory action potentials were absent in the right ulnar, median and sural.
