Elevation of plasma phenytoin by viloxazine in epileptic patients: a clinically significant drug interaction

F Pisani, A Fazio, C Artesi, M Russo, R Trio, G Oteri, E Perucca, R Di Perri

Abstract
The effect of viloxazine (150–300 mg daily for 21 days) on plasma phenytoin levels at steady state was examined in 10 epileptic patients stabilised on a fixed phenytoin dosage. After starting viloxazine treatment, plasma phenytoin concentrations increased by 37% on average (range 7–94%) from a mean value of 18.8 μg/ml at baseline to a mean value of 25.7 μg/ml during the last week of combined therapy. In four patients the rise in plasma phenytoin was associated with the development of signs of phenytoin toxicity. Discontinuation of viloxazine resulted in return of plasma phenytoin towards baseline values and disappearance of the clinical symptoms. The mechanism of interaction probably involves inhibition of phenytoin metabolism by viloxazine. Careful monitoring of plasma phenytoin levels is recommended in patients treated with phenytoin who need to be started on viloxazine therapy.

Depression is more common among patients with epilepsy than in the general population.1 The treatment of depression in patients with seizure disorders, however, is troublesome because antidepressant drugs generally exert a pro-convulsant effect.2 Experimental and clinical data suggest that viloxazine may be non-epileptogenic or at least less epileptogenic than other available antidepressants.2,3 Therefore, viloxazine is likely to be preferred to other medication in the treatment of epileptic patients with associated depression. Based on the above considerations, establishing whether interactions occur between viloxazine and concurrently administered antiepileptic drugs is important. During a previous trial, we found that viloxazine may inhibit the metabolism of carbamazepine and may precipitate clinical signs of carbamazepine intoxication in epileptic patients.4,5 The purpose of the present study was to evaluate whether a similar interaction occurs with phenytoin.

Materials and methods
Ten patients with epilepsy (seven men, three women, age 42–72 years, see table), stabilised for at least three months on a constant dosage of phenytoin (Dintoina, Recordati, Milan) and with no history of non-compliance, gave their informed consent to take part in the study, which was approved by a local ethics committee. After a two week observation period, each patient was started on viloxazine (Viloxazin, ICI-Pharma, Milan), 50 mg three times a day orally for three days, increased thereafter according to toleration to 100 mg three times a day for a total treatment period of three weeks. The plasma concentration of phenytoin, the dosage of which was maintained unchanged throughout the study, was measured by enzyme immunoassay (EMIT) at weekly intervals before, during, and after viloxazine treatment. Comparison of phenytoin concentration values at different times during the study was made by analysis of variance. All values reported in the text are given as means (SD).

Results
All patients completed the study. Five subjects (patients 1, 3, 4, 7, 9) reported transient gastric discomfort or general obtundity, or both, during the first week of viloxazine therapy, and their initial daily dose (150 mg) remained unaltered for the duration of the study. In all other cases viloxazine dosage was increased on day four to 300 mg daily without untoward effects, except for patient 5 who developed symptoms of gastric irritation and required a reduction in viloxazine dosage to 200 mg after two further days. Mean plasma phenytoin levels at different times during the study period are shown in the table. After intake of viloxazine, plasma phenytoin levels rose from a mean value of 19 μg/ml at baseline to a mean value of 26 μg/ml after two weeks on combined therapy. Although a rise in plasma phenytoin was observed in all patients, the magnitude of the percentage increase (37% on average) showed considerable interindividual variability, ranging in different subjects from 7% to 94%. Twelve to 16 days after initiation of viloxazine treatment, four patients presented with clinical symptoms (ataxia and nystagmus) suggestive of phenytoin intoxication. The plasma concentrations of phenytoin at that time in these patients were 32-3, 39-6, 36-2, and 41-0 μg/ml, which are well within the toxic range (table). In each of these cases, viloxazine was discontinued prematurely, resulting in a rapid decrease in plasma phenytoin and disappearance of the clinical symptoms. A decrease of plasma phenytoin levels towards baseline...
values was observed in all patients after viloxazine withdrawal.

**Discussion**

Our findings clearly show that administration of viloxazine to patients with epilepsy may cause a considerable elevation in plasma phenytoin levels at steady state. The effect is apparent within one week of viloxazine therapy and is clearly of clinical relevance, as indicated by the occurrence of reversible manifestations of phenytoin toxicity in four out of 10 patients. The interaction was observed at dosages of viloxazine which are within the range commonly recommended for the treatment of depression.10 These dosages are probably therapeutically adequate in patients treated with anticonvulsants as the pharmacokinetics of viloxazine are not affected by concurrent administration of antiepileptic drugs.11

Our observations agree with previous unpublished anecdotal reports, suggesting that viloxazine can be included in the long list of drugs which are known to increase plasma phenytoin levels in epileptic patients.12 As the oral bioavailability of the pharmaceutical preparation of phenytoin used in our patients is virtually complete (Recordati SpA, Milan, data on file), the increase in plasma drug concentration after administration of viloxazine cannot be ascribed to increased absorption and is probably due to inhibition of the oxidative metabolism of phenytoin in the hepatic microsomes. This interpretation is supported by previous findings by our group, providing evidence that viloxazine may inhibit two separate steps of carbamazepine metabolism—that is, oxidation to carbamazepine-10,11-epoxide and conversion of the epoxide to the corresponding dihydrodiole.9 The interference of viloxazine with carbamazepine-10,11-epoxide is of particular interest because phenytoin metabolism also involves formation of an epoxide intermediate.13

The magnitude of elevation in plasma phenytoin levels showed a wide interpatient variability (from a minimum of 7% to a maximum of 94%) and was not apparently related to viloxazine dosage. This variability could be related to interindividual differences in viloxazine pharmacokinetics11 or to the dose-depend-
