stroke, Orgaran is superior to low-dose heparin.

Our main conclusion, that the available randomised trials included in our overview were not designed to determine whether or not antithrombotic therapy with aspirin, heparin, or other agents are safe and effective when used in patients with acute stroke, is unaltered and will remain so until the large trials in progress (IST, TOAST, National Study of Stroke in China, MAST-I) are completed.

Mast trials

The study by Morris et al 1 on recruitment for acute stroke treatment trials of patients with stroke admitted to hospital illustrates, not treatment eligibility, should these treatments be proven to work, but simply how an artificially restrictive selection process can hinder trial recruitment.

In their study, the two trials compared have very different exclusion criteria, not dictated simply by the standard contraindications to the treatments being tested, and are addressing very different questions. In the International Stroke Trial (IST) all types of acute ischaemic stroke are eligible up to 48 hours after onset unless severely disabled or there is a clear contraindication to aspirin or heparin, such as active duodenal ulcer. The aim of the IST is to answer the simple question: Do aspirin or heparin, or both improve outcome after acute ischaemic stroke? The trial was designed to include as heterogeneous a group of patients with acute stroke as possible, so that in future, physicians would know accurately the risks and benefits of aspirin and heparin treatment when treating almost any such patient.

In contrast, the Multicentre Acute Stroke Trial (MAST), to which Morris et al referred, a very restricted question is being asked: "Does streptokinase improve outcome after major middle cerebral artery (MCA) territory ischaemic stroke if started within six hours?" Consequently the result of this trial will only apply to a very restricted group of patients with acute stroke—those with major MCA occlusion reaching hospital in time to be examined, investigated and treatment started within six hours. In other words, the trial design presupposes that streptokinase will not work after six hours, or in small cortical, or lacunar, or posterior circulation strokes. It will not yield any information on whether aspirin should be used as well as streptokinase, or avoided. These presuppositions are foolish, especially as we already have the example of the large myocardial infarction trials in determining thrombolysis and aspirin beyond six hours from symptom onset, and in a very heterogeneous group of patients with acute myocardial infarction, it was possible to show a true time window to treatment (12 hours), the effect of age (benefit at all ages) and that thrombolysis and aspirin together work better than either individually.2 3

No wonder then, that the patients in the study by Morris et al were excluded from their streptokinase trial: 50% presented after six hours; 23% had a previous cerebrovascular accident with residual clinical deficit; 15-5% had a lacunar infarct; 5-5% had posterior circulation ischaemia; 22-5% had other serious systemic illness (nature not specified). In fact only 32 (haemorrhage on CT), two (tumour on CT), one (streptokinase in the past year), seven (warfarin treatment), two (pregnancy), 13 (bleeding tendency or DI), nine (transient ischaemic attack), 12 (not clinical stroke) had true contraindications to streptokinase and most of these were potentially-ineligible for the IST for the same reasons.

Who are we clinicians to decide, on the basis of no evidence,1 however, that patients with a previous cerebrovascular accident, or who reach hospital after six hours (most patients with stroke in the United Kingdom) or who have a lacunar or mild cortical infarct, etc, are unlikely to benefit from a particular acute stroke treatment, never mind thrombolysis? If treatments are not tested in a practical manner in a representative group of patients, then the trial result will never be applicable to the generality of patients who suffer an acute ischaemic stroke, and important benefits may be missed.

It is important to understand that the MAST trial described by Morris et al is not the same as the Multicentre Acute Stroke Trial—Italy (MAST-I). MAST-I is the largest randomised controlled trial of thrombolysis in acute ischaemic stroke groups. It is far, with more than 440 patients randomised (most in Italy but some in the United Kingdom) and strong encouragement from its Data Monitoring Committee not only to complete the trial but also to expand the pilot and enhance recruitment. MAST-I is testing streptokinase, aspirin, both or neither (like the Italian Group Studying Streptokinase in myocardial infarction (GISSI) and ISIS-2)3 in all types and severities of acute ischaemic stroke. It has a six-hour time window to treatment which is likely to be extended in the near future. At the end of MAST-I, a physician faced with a patient with stroke will have useful information on the risks and benefits of streptokinase and aspirin, together and separately, applicable to that individual patient.

Clinical trials should be designed to answer practical questions on the risks and benefits of treatments for as many patients as possible, especially for conditions as common as acute cerebral stroke. Let us not make the mistake of equating trial eligibility with treatment eligibility, nor make assumptions about when promising, but largely unproven4 results are likely to work. The lessons from the acute myocardial infarction trials of thrombolytic and antithrombotic drugs should not be ignored. Until a treatment is found that works, acute ischaemic stroke treatment trials should proceed in the most practical and sensible manner possible, by adhering wide entry criteria and avoiding presuppositions about the effects of treatment.

J M WARDLAW
Department of Clinical Neurohaematology, Southern General Hospital, 1345 Groom Street, Glasgow G51 4TF, UK

Dr Lees et al reply:

We thank Dr Wardlaw, who is the United Kingdom representative of MAST-I, for her letter. Despite her criticism of the cautious entry criteria for the international version of MAST, more patients have been randomised to MAST than to MAST-I in the United Kingdom.

We agree that stroke trials should adopt wide entry criteria without prejudicing the results. We also believe, however, in restricting exposure to potentially dangerous treatments to patients in whom the risk/benefit ratio justifies intervention. We are not prepared to disregard evidence regarding treatment from experimental studies, large clinical studies of thrombolysis after acute myocardial infarction and pilot studies after stroke. The selection of a homogeneous group in whom the risk of thrombosis or bleeding tendency is aimed at maximising the chance of a statistically meaningful result.

Experimental evidence suggests that the therapeutic window for successful neuroprotection through reperfusion is under six hours.1 Although the ISIS-3 study reported intracerebral haemorrhage in under 1% of patients treated with thrombolysis after myocardial infarction, the incidence of fatal intracranial haematoma in pilot studies of thrombolysis after stroke has been up to 10%.2 Haemorrhage was less common in patients treated within 90 minutes of stroke onset.3 Outcome after stroke is variable, but generally much better after lacunar or small cortical infarcts than after large MCA infarction. Inclusion of patients with ineligibility on outcome (stroke) as a variable, but generally much better after lacunar or small cortical infarcts than after large MCA infarction. Inclusion of patients with ineligibility on outcome (stroke) as a variable, but generally much better after lacunar or small cortical infarcts than after large MCA infarction. Inclusion of patients with ineligibility on outcome (stroke) as a variable, but generally much better after lacunar or small cortical infarcts than after large MCA infarction.
