LETTERS TO THE EDITOR

Carbamazepine in the treatment of generalised tonic clonic seizures in juvenile myoclonic epilepsy

Juvenile myoclonic epilepsy is characterised by bilateral myoclonic jerks on waking, and generalised tonic clonic seizures with onset in the mid-teens, which may be preceded by absences in 33% of patients.¹ Findings on EEG include bilateral spikes or multiple spike-slow wave discharges at 4-6 Hz with a normal background; about 30% of these patients show photosensitivity or focal abnormalities, or both.²

A particularly good long-term prognosis exists if compliance with valproate, the drug of choice for the treatment of juvenile myoclonic epilepsy, is maintained.³,⁴ In the 8-20% of patients in whom control cannot be achieved with valproate treatment alone, low doses of the second-line antiepileptic drug clobazam, or phenobarbital may be needed.³,⁵ Carbamazepine is not indicated for juvenile myoclonic epilepsy, with some reports suggesting that it may actually exacerbate seizures.⁶ In view of this consensus it was of particular interest to us that in two patients with juvenile myoclonic epilepsy, generalised tonic clonic seizures but not absences or myoclonic jerks were controlled only after carbamazepine was added to valproate treatment.

CASE 1

This woman, aged 32 years, whose mother also has generalised tonic clonic seizures, has late onset congenital adrenal hyperplasia and juvenile myoclonic epilepsy with photosensitivity. Her first generalised tonic clonic seizure at the age of 14 years was induced by television; all others occurred on waking. Generalised tonic clonic seizures were controlled by carbamazepine (400 mg/day, plasma concentration 34 μmol/l), only six having occurred in 13 years, but violent myoclonic jerks on waking and frequent, inconspicuous typical absences were present. Clinical examination was normal and EEG findings were consistent with juvenile myoclonic epilepsy and photosensitivity, but showed some inconsistent focal abnormalities. During her first pregnancy at the age of 29 years, the myoclonic jerks disappeared. Within a few days of the birth of a healthy son, they returned every morning after waking, and were present enough to make her drop her baby. Six months later she had her first generalised tonic clonic seizure in three years. Juvenile myoclonic epilepsy was diagnosed and valproate (275 mg/day) added. This fully controlled the myoclonic jerks and absences, and carbamazepine was withdrawn completely over two months. Three weeks later she had a second generalised tonic clonic seizure upon awakening, with a short period of sleep-deprived. Carbamazepine (400 mg/day increasing to 600 mg/day) was then added. The remainder of the pregnancy was uneventful and no generalised tonic clonic seizures, myoclonic jerks, or absences have occurred for 29 months, despite decreasing the valproate dose to 1000 mg/day.

CASE 2

This 20 year old woman, had a febrile convulsion at the age of 3-5 years. Typical absences, myoclonic jerks, and generalised tonic clonic seizures occurred in her mid-teens with no particular circadian distribution. The seizures were spontaneous or precipitated by television, video games, anger and emotion, and sleep deprivation. Neurological examination and MRI were normal. Results of EEG support a diagnosis of juvenile myoclonic epilepsy with photosensitivity, but marked alternating focal abnormalities were also found in follow-up EEGs.

Valproate (1 g/day) controlled the generalised tonic clonic seizures initially but had little effect on the myoclonic jerks, and produced a large weight gain. Phenytoin made her hirsute and reduced the concentration of 5-4 μmol/l of was of no benefit. At her first visit to us she was taking valproate (1200 mg/day; plasma levels >306 μmol/l), clonazepam (1 mg/day), and phenytoin (250 mg/day), and a recent pre-examination stresses her myoclonus was worsening. A previous two week trial of carbamazepine (400 mg/day) alone had been unhelpful. Phenytoin was withdrawn slowly. With the combination of valproate (1500 mg/day) and clonazepam (1.5 mg/day) absence were minimised, myoclonic jerks were nocturnal only, but the generalised tonic clonic seizures persisted. Carbamazepine (1200 mg/day) was added to this regimen without side effects and no further generalised tonic clonic seizure has occurred in 15 months.

These cases of definite juvenile myoclonic epilepsy and photosensitivity show that carbamazepine combined with valproate is more effective than valproate alone or with clonazepam in preventing generalised tonic clonic seizures. Carbamazepine alone did not prevent generalised tonic clonic seizures, myoclonic jerks, or absences in the young patient although valproate was efficacious against the latter seizure types, the combination of the two drugs was necessary for full generalised tonic clonic seizure control. Interestingly, these two patients had some focal abnormalities on EEG in addition to findings typical of juvenile myoclonic epilepsy. Valproate is the acknowledged drug of choice for treatment, producing a rapid and sustained reduction or abolition of generalised tonic clonic seizures, myoclonic jerks and absences in more than 80% of patients.⁷ In those rare instances in which generalised tonic clonic seizures prove recalcitrant to treatment, however, and particularly if there is some evidence of focal discharges at EEG, the combination of valproate with carbamazepine may improve side effects. These patients exemplify the need for syndrome-related drug trials and for a consideration of possible pharmacological interactions between drugs used to treat epilepsy.

Intracranial chordoma with a novel symptom

The case is described of a novel presentation of an adult with an intracranial chordoma. The onset was relatively acute with neck pain and lower cranial nerve involvement producing an unusual symptom related to head movement and posture. The tumour has followed an aggressive course in spite of radical surgery and radiotherapy.

A 40-year-old man presented with cervical and occipital pain which had persisted for four months. No neurological deficit was found and a diagnosis of cervical spondylosis was made. Plain radiographs of the craniovertebral junction and neck were normal.

Two months later he presented again, reporting that on flexing his neck or lying horizontal he could not make the tongue properly and was unable to speak. These symptoms resolved within 30 seconds of sitting up or raising his head. He was referred to the neurological department where wasting of his tongue, more marked on the right, with deviation of the median raphe to the right was noted. An inability to speak and to move his tongue on flexing the neck was confirmed but language seemed to reach the pin-prick was normal. The remainder of the neurological examination was normal and ear, nose, and throat assessment confirmed normal palatal movement and sensation.

After a few weeks his neck pain and the positional symptoms affecting his tongue resolved and were replaced by persistent dysarthria with difficulty in propelling saliva, food, or liquid out of his mouth. There was no choking or nasal regurgitation. During this period he developed wasting of the extensor neck muscles, especially on the left side, and of the sternocleidomastoids.

Enhanced CT and MRI showed a destructive mass lesion, thought to be a chordoma, extending from the clivus to the anterior margin of the foramen magnum. A transoral resection of the tumour was performed and complete clearance was felt to have been achieved. Histology showed the characteristic appearance of a chordoma, masses of chondroid cells, often with vacuolated "bubbly" cytoplasm (physaliphorous cells) and uniform round nuclei, were surrounded by a plentiful mucinous matrix.

The patient made a good recovery after the operation, with some improvement of speech and swallowing. There was residual wasting and weakness of the tongue. Six months after the operation he had returned to his normal work and power of the sternomastoids and neck extensor muscles had almost returned to normal.

Three months after the operation the patient developed diplopia, his swallowing started to deteriorate again, and his voice became hoarse. At this time he was noted to have a partial left sixth nerve palsy and a left Horner’s syndrome.
