SHORT REPORT

Focal hand dystonia in a patient with thoracic outlet syndrome

A Quaratarone, P Girlanda, G Risitano, G Picciolo, S Sinicropi, C Nicolosi, V Macaione, C Messina

Abstract

A patient affected by thoracic outlet syndrome, with an involvement of the left lower primary trunk due to a rudimentary cervical rib, developed a severe hand dystonia on the same side. The dystonic posture was characterised by a flexion of the wrist with the fingers curled into the palm. Polygraphic recordings performed on the left flexor digitorum superficialis (FDS4) and extensor digitorum superficialis (EDC4) muscles, during a repetitive tapping task of the fourth digit, showed a loss of well formed bursts without a clear silent period along with long duration bursts of cocontraction in antagonistic muscles. The study of reciprocal inhibition between forearm flexor and extensor muscles showed a reduced amount of inhibition in both the disynaptic and the later presynaptic phase of inhibition. The patient underwent an operation with resection of the cervical rib. Twelve hours after the operation the patient experienced a significant improvement of the hand dystonia; the dystonia had disappeared completely by two months with a progressive normalisation of reciprocal inhibition.

Keywords: thoracic outlet syndrome; focal dystonia; reciprocal inhibition cocontraction

An increasing number of reports have focused attention on the importance of trauma as a cause or precipitant factor of movement disorders. It has now been well established that trauma to the CNS can cause Parkinson’s disease, tremor, and dystonia.\(^1\)\(^2\) On the contrary the effect a peripheral nervous system disease has on the pathogenesis of movement disorders such as myoclonus,\(^3\) painful legs and moving toes disease,\(^4\) and Parkinson’s disease\(^5\) is less clear. More recently, there have been numerous papers describing the association of soft tissue injury, mononeuropathy, radiculopathy, and plexopathy with focal dystonia.\(^6\)\(^7\) A high incidence of ulnar neuropathy has been found in musician’s cramp. In these patients the focal dystonia improves and worsens in parallel with fluctuations of ulnar neuropathy.\(^8\) This report is on a patient affected by a plexopathy due to a thoracic outlet syndrome, who developed a severe focal hand dystonia on the same side, which improved dramatically after operation.

Case report

We describe a young man who had been complaining of intermittent pain and paraesthesias along the medial aspect of the left arm and forearm for the past two years. In the past six months, he has also experienced numbness of the fourth and fifth digits of the left hand, associated with hand weakness and difficulty in the performance of flexion and extension movements of the wrist. Neurological examination disclosed a mild wasting of hypothenar muscles associated with a dystonic posture of the left hand characterised by a flexion of the wrist and curling of the fingers into the palm. A patchy sensory loss was detected along the medial aspect of the left forearm extending into the fourth and fifth digit. In particular, vibration sense, joint position, and two point discrimination was lost. Neck radiography disclosed the presence of a bilateral rudimentary cervical rib as well as a bilateral elongated transverse process of C7. The Addson test was negative. Arteriography showed only a mild spasm of the subclavian artery. Electroneurographic studies disclosed a reduced median nerve compound motor action potential (CMAP) recorded from the abductor pollicis brevis, a reduced sensory nerve action potential (SNAP) recorded from the ulnar nerve, and a prolonged latency of F wave in hypothenar muscles on the left side. Conduction velocity reduction was not detected along the ulnar nerve at the elbow. Concentric needle EMG suggested chronic partial denervation in the muscles supplied from C8 and T1. The somatosensory evoked potentials, after stimulation of the ulnar nerve, showed an increased N9-N13 interpeak conduction time after stimulation on the left side. Gadolinium enhanced MRI of the brachial plexus and cervical spinal cord was normal. Polygraphic surface recording performed on the left flexor digitorum superficialis (FDS4) and extensor digitorum superficialis (EDC4) muscles, during a repetitive tapping task of the fourth digit, demonstrated a loss of well formed bursts without a clear silent period along with long duration bursts of cocontraction in antagonistic muscles

Discussion

The electrophysiological findings were consistent with the diagnosis of thoracic outlet syndrome with an involvement of the primary low trunk of the left brachial plexus. The patient also presented a dystonic posture of the left hand with loss of speed and fluency of movement, which improved dramatically after surgical operation. The activity in FDS4 and in EDC4 muscles recorded via surface electrodes after a tapping task of the fourth digit disclosed a dystonic cocontraction pattern that was confirmed by the reciprocal inhibition technique. This report shows that the peripheral nervous system could be involved in the determinism of focal hand dystonia. This is supported by the fact that surgical operation relieved the hand dystonia with a progressive normalisation of the reciprocal inhibition. The notion that peripheral nervous system involvement alters sensory input, inducing central cortical and subcortical reorganisation, generating movement disorders, has received support from recent experimental studies. Sanes et al10 found a reorganisation of cortical motor outputs from the shoulder area after forelimb amputation in adult rats. Merzenich et al11 discovered that median nerve section in adult monkeys rendered the area of median nerve cutaneous representation in the sensory cortex responsive to radial and ulnar stimulation. Plasticity of the motor cortex has also been reported in humans after amputation or anaesthetic block.12 However, the mechanism underlying CNS plasticity after peripheral nerve injury is still open to speculation. Focal hand dystonia is characterised by a reduction in ipsilateral reciprocal inhibition due to a dysfunction of interneurons responsible for such inhibition at the spinal level.13 Activity in these interneurons is regulated by cortical control and by the peripheral input from Ia afferents. Stimulation of Ia afferents, using a high frequency vibration applied to the tendon and muscle belly, partially reproduces the symptoms in patients with writer’s cramp.14 These data suggest that focal dystonia is influenced by tactile and proprioceptive sensory inputs. The findings obtained in our patient agreed with the data described in the literature. We hypothesise that a focal demyelination within the brachial plexus of our patient produced an ephaptic activation of cutaneous and muscle afferents. We maintain that the chronic activation of cutaneous and Ia afferents may alter reciprocal inhibition at a spinal level, thus inducing EMG abnormalities similar to those seen in dystonia. The surgical operation may have been responsible for breaking this vicious circle, thereby relieving the hand dystonia.
