LETTERS TO THE EDITOR

Complex partial seizures provoked by photic stimulation

In patients with known or suspected epileptic seizures, non-specific activation methods such as hyperventilation or intermittent photic stimulation (IPS) are used to provoke epileptiform potentials, which may prove the epileptic nature and specify epileptic syndromes. A photoconvulsive reaction with generalised spike wave activity may be provoked by IPS and is almost confined to patients with generalised epilepsy. There are, however, some reports on patients with partial epilepsy. In our experience, negative IPS did not exclude the diagnosis of photoconvulsive reaction, who developed these with focal epileptic discharges consequent to IPS and discuss possible mechanisms.

Patient 1, a 44 year old woman presented with a 33 year history of complex partial seizures starting with behavioural arrest followed by oromotor automatisms, which were sometimes followed by secondary generalisation. She was treated with carbamazepine and reported 1–2 seizures a month. Brain MRI failed to disclose any focal abnormality. Except for mild generalised slowing (7.5/s), probably due to or accentuated by carbamazepine, focal slowing (5–4/s) with phase inversion over F8, was seen in two EEG recordings (average of 1 spike in 7 minutes). During hyperventilation (3 minutes) the number of spikes increased to an average of 1 spike in 1 minute. During IPS (started with 1/s duration), the number of single spikes increased to 6 in 3 minutes or 2 per minute (figure). During the second recording, the spike activity in the anterotemporal region finally became rhythmic with subsequent generalisation. This was accompanied by a complex partial seizure typical for this patient (behavioural arrest followed by oromotor automatisms) finally running into a generalised tonic-clonic seizure.

Patient 2 was a 19 year old woman who had complex partial seizures with secondary generalisation for 2 years. The seizures started with fear (“indescribable terror”) accompanied by a fearful expression. This was followed by a repetitive ictal speech which was sometimes followed by secondary generalised tonic-clonic seizure. She reported one of these seizures as a consequence of flashing lights in a discotheque and avoided flashing lights since then. She was treated with valproate and reported 4–5 seizures per year. MRI was normal. EEG disclosed focal slowing (4 cps) with phase inversion over T6, which corresponded to decreased perfusion of the right midtemporal and parietotemporal regions established by HMPAO-SPECT. Intermittent photic stimulation (12/s) evoked a photoconvulsive reaction with bifrontal accentuated generalised spike-wave activity associated with myoclonic eyelid jerks. Independent of photoconvulsive reaction, 8 seconds later on single sharp-wave activity with phase inversion over T4, occurred consequent to IPS and became rhythmic. This was associated with complex partial seizures starting with fear accompanied by a terrifying fearful expression, which were followed by ictal speech (repetition of single words) finally running into a generalised tonic-clonic seizure.

Both patients developed complex partial seizures with secondary generalisation resulting from IPS and one of them reported a complex partial seizure provoked by flashing light in a discotheque. To our knowledge, neither complex partial seizures nor activation of temporal epileptic activity consequent to IPS have previously been reported. Specific stimuli like rubbing, cold wind, or tactile stimuli may evoke spike activity in the contralateral cerebral regions and provoke partial seizures. Even patients with myoclonic epilepsy may develop contralateral spikes after electrical peripheral nerve stimulation. In all these patients, spike potentials were evoked in primary cortical representation areas of the respective stimuli. Our patients showed provocation of anterotemporal (F7, patient 1) and posterotemporal (T6, patient 2) epileptic activity resulting from IPS, which may have been adjacent to the visual cortex in patient 2 but was distinctly apart from the primary visual cortex in patient 1. Complex partial seizure symptomatology in the first patient included oromotor automatisms, indicating a seizure origin in the amygdalohippocampal complex. Visual hallucinations, which are likely with epileptic discharges in the visual cortex or visual association areas, however, were missed. This indicates that provoked complex partial seizures during IPS in our patients occurred without epileptic activity in the visual cortex. Temporal epileptic activity as a consequence of IPS was probably mediated via occipitotemporal connections such as the fasciculus longitudinalis inferior.

Provocation of sharp waves with phase inversion over F8 and the occurrence of a photoconvulsive reaction in patient 2 raises the question whether both phenomena were
interrelated. Similar constellations were previously reported in individual patients with photoconvulsive reaction who had partial epilepsy and occipital epileptic focus. Cortical and subcortical recordings in monkeys during IP showed paroxysmal discharges predominantly in prerolandic areas, which were followed by bursts in the pontine and mesencephalic reticular formation and, finally, by generalised discharges. These findings have been interpreted in favour of a cortical origin of the photoconvulsive reaction, which is supported by the studies of Ricci et al using neuromagnetic methods in humans with photoconvulsive reaction to identify the location of the photoconvulsive reaction generator. They found a regional sensitivity involving frontal, occipital, and temporal areas, but the cortical excitability was extremely unstable, which was attributed to a deficient GABAergic system. This suggests that photoconvulsive reaction is a generalised phenomenon and not due to polyfocal generation. The occurrence of focal epileptic discharges associated with focal seizures and secondary generalisation in patient 2 does not indicate a relation between focal epileptic discharges and the photoconvulsive reaction as the second appeared in only one of the patients.

Creutzfeldt-Jakob-like syndrome induced by lithium, levomepromazine, and phenobarbitone

Creutzfeldt-Jakob-like syndrome was first reported by Smith and Kocen in 1988. Its symptoms resemble Creutzfeldt-Jakob disease but it is induced by drugs, particularly lithium, and most patients recover without sequel after discontinuation of drugs. It also displays a characteristic EEG similar to Creutzfeldt-Jakob disease, but this returns to normal when the patient recovers.

There have been some case reports of Creutzfeldt-Jakob-like syndrome after that of Smith et al (table), but no paper seems to have described the detailed course of EEG changes. This paper presents a case of Creutzfeldt-Jakob-like syndrome possibly induced by lithium, levomepromazine, and phenobarbitone, in which we succeeded in recording the course of EEG changes.

A 65 year old woman was admitted to a hospital with coma and myoclonus. She had a history of manic and depressive disease for 8 years and had been treated with 200 mg lithium carbonate, 25 mg chlorpromazine, and 10 mg levomepromazine daily. Her first symptom was forgetfulness from 20 May, then she complained of appetite loss from 29 May, diarrhoea from 1 June, myoclonus from 3 June, and gait disturbance from 4 June. At the same time she complained of visual disturbance. Gradually her conscious level declined. When she was admitted to the hospital on 4 June, she had convulsions. At that time, she was injected with 200 mg phenobarbitone intramuscularly and this was continued for 2 more days at the same dose. Physical examination disclosed no abnormality. Neurologically there was general hypotonia and hyporeflexia without Babinski's sign. Serum glutamic oxaloacetic transaminase, glutamic pyruvic transaminase alkaline phosphatase, and creatine kinase was increased slightly, and serum ammonia was 64 µmol/l (normal range 30–59 µmol/l). Plasma sodium and potassium concentrations were normal. Her creatinine clearance was 46 ml/min and thyroid function was normal. Examination of CSF gave normal results. Chest radiography, brain CT, and brain MRI showed no abnormality. ECG showed T wave inversion from V1 to V3. The EEG showed slow basic activity but no periodic discharge on 4 June, but showed PSD on 7 June (figure).

Its periodicity decreased on 10 June and had returned to her previous EEG on 19 June. Her ECG had also returned to normal by 14 June. Her myoclonus disappeared on 6 June, and her conscious level gradually improved from 9 June; she could open her eyes on 10 June, then she could answer our questions regarding place and time and could walk without help from 13 June. She was discharged on 25 June fully recovered.

She was diagnosed as having Creutzfeldt-Jakob-like syndrome induced by lithium,

Li= lithium, SL= serum lithium concentration; PD= periodic discharge, T= toxic, NT= not toxic, NA= not assessed, Madip*=levodopa/benserazide.

EEG on 4, 7, 10, and 19 June. It shows PSD on 7 June. The amplitude of the PSD is 150–200 µV and the frequency is 1.5–2 Hz.
chloropromazine, levomepromazine, and pheno- borebitone. Her CSF lithium concentration was 0.82 mmol/l on 4 June. According to Taguchi et al., lithium concentration in CSF is about one fourth of the serum concentra- after taking lithium for more than 1 week, and it was postulated that a serum lithium con- centration is toxic above 1.5 mmol/l, so her serum concentration is likely to be high enough to be toxic. Her symptoms such as forgetfulness, diarrhoea, coma, myoclonus, and visual disturbance were all compatible with lithium intoxication. The cause of her high lithium concentration was clear with the discovery that she took three times as much as prescribed when she could not sleep well. Periodic EEGs and routine CSF examinations diverged 3 days after all the drugs were discontinued and was displayed for about 3 days. There are some case reports of Creutzfeldt-Jakob-like syndrome induced by chloropromazine and levomepromazine, but there are apparently no reports of its induction by pheno- borebitone. We could not identify the role of pheno- borebitone injected from 4 to 6 June, but it was possible it might have some part in the induction of PSD, and her hypotension and hyporeflexia are uncon- sumed compared with previous reports.4 In conclusion, this drug induced Creutzfeldt- Jakob-like syndrome showed us the importance of taking a drug history, as previ- ously pointed out by Smith et al. 4

Central nervous system involvement in a novel connexin 32 mutation affecting identical twins

Connexin 32 (Cx32) is a gap junction protein expressed in the peripheral nervous system (PNS), central nervous system (CNS), and in many other tissues.1 Mutations in the Cx32 gene are associated with X-linked Charcot-Marie-Tooth disease (CMTX), and account for about 10% of the patients with hereditary motor and sensory neuropathy (HMSN).

At least 130 different mutations have been reported in the Cx32 gene causing peripheral neuropathy. Classically, distal weakness and atrophy initially involving the lower limbs, as well as sensory abnormalities, depressed tendon reflexes, and pes cavus are usually found in males by the second decade, whereas in carrier females clinical manifestations, if present, are in most instances milder than in affected males. Nerve conduction studies in affected males are usually, but not always, suggestive of a demyelinating process, al- though they are not quite as slow as in patients with CMT1A. In females, conduc- tion velocities (CVs) may be in the normal range or only mildly reduced, as seen in axonal neuropathies.

We describe a new Cx32 point mutation (Ala10Val) in genetically established identical twins with similar CMT phenotypes and extensor plantar reflexes. The probands were first seen at the age of 20. Their principal complaint was cramps in the legs, “going over” on the ankles, and mild weakness in the hands. On examination, Twin 1 could not stand on his heels and had a mild intrinsic hand muscle weakness. There was a mild distal atrophy in both upper and lower limbs. Pinprick and tactile sensations were diminished up to the knees and vibration was impaired distally in the lower limbs. Tendon reflexes were present or increased, but both plantar responses were extensor. His median, ulnar, and peroneal motor CVs were 33.0 m/s, 33.0 m/s, and 31.0 m/s, respectively, and the distal amplitudes were 0.7 mV, 5.0 mV, and 3.3 mV. The sensory potentials were all absent. Twin 2 had identical clinical manifesta- tions, except that the left plantar reflex was flexor whereas the right was clearly extensor. His motor CVs and amplitudes of the same nerves described above were 30.0 m/s and 1.7 mV, 34.0 m/s and 6.0 mV, and 33.0 m/s and 4.0 mV, respectively. No sensory response was obtained. Their mother had minimal neuropathic features and both plantar re- flexes were extensor. Her median and pero- neal motor CVs were 43.0 m/s and 37.0 m/s, and the median sensory CV was 40.0 m/s. Their sister and the mother’s brother were clinically and electrophysiologically normal. The maternal generation was not examined, but had a long history of a slowly progressive neuropathy.

The presence of the 17p11.2-p12 duplication was excluded by fluorescent quantita- tive polymerase chain reaction with five micro- rosilicate markers contained within the involved segment.

Sequencing Cx32 with the ABI™ Dye Primer Cycle Sequencing Ready Reaction Detecto a C to T transition (figure) at amino acid 39 causing an alanine to valine substitution in the first extracellular loop. This mutation abolishes a restriction site for the enzyme BstXI and oligonucleotide sequencing 200 control chromosomes and the father’s DNA, no mutation was found. The mother was shown to harbour the mutation.

The monozygosity status of the twins was confirmed by restriction digestion of the same alleles at each of the 13 highly polymorphic microsatellite markers tested. The possibility of this occurring by chance is >0.01%.

The presence of a Babinski’s sign in our fam- ily with a mutation on code 93 whose clinical manifestations included tremor, brisk re- flexes and spasticity. On MRI there was atro- phy of the cerebral cortex and cerebellum. The presence of a Babinski’s sign in our fam- ily strongly suggests that in this novel mutation there is involvement of the corticos- pinal tract. Unfortunately no imaging or evoked potential studies were possible.

Cx32 is a gap junction protein expressed in the paranodal region and Schmidt- Lantermann incisures in the PNS, and in cell bodies and oligodendrocytes processes in the CNS. Why mutations in Cx32 usually lead only to PNS dysfunction is still an open question. Presumably, there is a unique rela- tion between Cx32 and the structural organ- isation or metabolic requirements of the PNS. Another possibility is that other connexin proteins might compensate for Cx32 dysfunction in the CNS and other tissues, but not in the PNS.

Although the clinical manifestations are extremely similar in most of the Cx32 neuropathies suggesting that different muta- tions do not cause different phenotypes, different degrees of severity and the presence of unusual signs, like the one we present here,
have already been described to occur with some mutations.

There are only two previous reports relating to three pairs of identical twins with CMT and known genetic defects. In the two pairs with the 17p11.2 duplication there was remarkable clinical variability. We have also seen a pair of identical twins with a P0 mutation in whom there was marked variability in early ages (unpublished data). Apart from the asymmetry of toe responses in one twin which is common in the probands, the genetically identical twins described here are phenotypically very similar, suggesting that the expression of this mutation was not influenced by other non-genetic factors.

Codon 39 seems to be of particular importance to Cx32 protein function as changing of the wild type amino acid has caused CNS dysfunction in addition to the peripheral neuropathy. Moreover its expression does not seem to depend on non-genetic factors, as might be expected from a hemizygous condition.

Isolated ischaemia of the spinal cord due to bilateral vertebral artery dissection

Clinical features in vertebral artery dissection are rarely associated with an ischaemic lesion of the spinal cord. The few cases related and studied with MRI strictly involve the cervical cord. 1,2 We add another patient with spontaneous bilateral vertebral artery dissection in whom the particularity was an isolated extensive ischaemia of the spinal cord from C4 to T5 vertebral levels.

A previously healthy 45 year old woman had paresthesia of the right ankle lasting a few days. Ten days later, she had a right sided scapulothoracic pain and suddenly developed a predominantly right sided tetraparesis and urinary retention. There was no history of neck trauma. Cranial nerve examination was normal. There was a right sided hemiplegia and a moderate left sided hemiparesis. Deep tendon reflexes were normal, right plantar response was extensor. There were bilateral spinthalamic problems below T4 with loss of touch sense in the right leg. Thus the examination was consistent with atypical, right cervical Brown-Séquard’s syndrome.

Biological investigations were normal. CSF protein was 0.34 g/l, glucose 2.54 mmol/l (2.10–4.20 mmol/l). There were 7 white cells and 25 red cells/mm3.

There were no oligoclonal bands. The ECG was normal. There was no aortic dissection shown on CT or MRI. Visual evoked potentials were normal. Somatosensory evoked potentials were abnormal for the right lower limb at the cervical level. A sagittal T2 weighted MRI showed linear cord high signal from C4 to T5 vertebral levels consistent with an ischaemic lesion (figure). On corresponding axial cuts, this was shown to involve the region of the anterior horns at cervical level and to prevail on the right half of the spinal cord at dorsal level. MRI of the cerebellum and brain stem was normal. Cerebral angiography showed an irregular stenosis of the right and left cervical vertebral artery typical of a dissection. The patient was treated with oral anticoagulants. One year later, the sequelae were a spastic paraparesis with right sided central pain and mild urinary retention. MRI and MRA showed the resolution of the cord signal and normal right and left vertebral artery.

The cervical cord is mainly supplied by radicular arteries rising from the vertebral artery. Thus, vertebral artery dissection can lead to an ischaemia limited to the cervical cord. Extensive ischaemia to the dorsal cord (T5) is uncommon. Our results suggest that this area is sometimes supplied from the vertebral artery.

Autonomic dysfunction and orthostatic hypotension caused by vitamin B12 deficiency

Orthostatic hypotension sometimes is a reversible neurological complication of vitamin B12 deficiency. 3,4,5 Eisenhofer detected deficient sympathetic catecholamine release in insulin tolerance testing, 6 but the mechanism of orthostatic hypotension in vitamin B12 deficiency remains unclear. We report a patient with vitamin B12 deficiency and reversible orthostatic hypotension and discuss the mechanism of this symptom.

A 77 year old man admitted to our hospital had had unstable gait and urinary urgency for 6 months, clumsiness of the hands and tingling sensations in the legs for 3 months, and, for a month, occasional dizziness on standing. The dizziness was mild without any attack of syncope. He had no other symptoms or signs of autonomic dysfunction but impotence and erectile failure were noted 10 years before the onset of neurological symptoms. He had not taken any medicine which would affect the autonomic nervous system. He did not have a habit of drinking.

Physical examination on admission detected no signs of anaemia, heart failure, or dehydration. Neurological examination showed dysaesthesia and decreased sensation of all modalities in the legs for 3 months, and, for a month, occasional dizziness on standing. The dizziness was mild without any attack of syncope. He had no other symptoms or signs of autonomic dysfunction but impotence and erectile failure were noted 10 years before the onset of neurological symptoms. He had not taken any medicine which would affect the autonomic nervous system. He did not have a habit of drinking.

over 30 mm Hg with normal heart rate response. His serum noradrenaline concentration was reduced at rest, and its increase after head up tilt was minimal. Sudomotor function was evaluated by sympathetic skin response (SSR) and local sweat response to acetylcholine (Ach).

Before treatment, the SSR amplitude was decreased, and the number and area of sweat droplets were decreased in responses to intradermal Ach injection. The myelinated fibre density of biopsied sural nerve was 5927/mm². Some thin myelinated fibres were present, as were a few myelin ovoids. Examination of the teased fibres showed evidence of demyelination (about 20%) and axonal degeneration (about 10%). Electron microscopy showed a normal unmyelinated fibre density (30 945/mm²); Collagen pockets (15 000 /mm²), and denervated Schwann cell subunits (12 000 /mm²) were present, but their densities were within the normal range for his age.1

A highly sensitive acetylcholinesterase (AChE) histochemical test (modified Tago’s method)2 of the sural nerve detected a slightly reduced density of sudomotor sympathetic unmyelinated fibres (3500 /mm²; normal 3700–6500/mm²). Daily intramuscularly administered 1 mg vitamin B12 for a week then 1 mg once a month increased its serum concentration rapidly to normal, resulting in the gradual amelioration of orthostatic dizziness, and his neurological symptoms except for erectile failure, after a month.

The abnormalities seen in the autonomic nervous system tests also disappeared when vitamin B12 was given for 6 months (table). The lesion of the baroreflex responsible for his orthostatic hypotension is considered to be in the efferent pathway because of the preserved heart rate response in head up tilt test. The low serum noradrenaline concentration in particular can be explained by disturbance of the sympathetic postganglionic fibres. These findings are supported by the decreased SSR amplitude and the reduced local sweat response to Ach. In contrast, the density of the unmyelinated fibres and AChE positive fibres were relatively well preserved when his age was considered. Furthermore, there was the rapid recovery of serum noradrenaline concentration, the SSR size, and the sweat response to Ach after giving the vitamin B12 supplement. These results suggest dysfunc-

Sandifer’s syndrome and gastro-esophageal reflux disease

Perkin and Murray-Lyon’s Neurology and the gastrointestinal system reviews gastrointestinal disorders with neurological features.1 The authors do not mention Sandifer’s syndrome, a disorder of the upper gastrointestinal tract with neurological manifestations occurring in children and adolescents. Sandifer’s syndrome is the association of gastro-esophageal reflux disease with spastic torticollis and dystonic body movements. Nodding and rotation of the head, neck extension, gurgling sounds, withstanding movements of the limbs, and severe hypotonia have been reported.2,3 It is hypothesised that such positioning provides relief from discomfort caused by acid reflux.4 A causal relation between gastro-esophageal reflux disease and the neurological manifestations of Sandifer’s syndrome is supported by the resolution of the manifestations on successful treatment of gastro-esophageal reflux disease.4–6 The clinical manifestations of this invariable occurrence of torticollis with alternating directions, normal sternocleidomastoid muscles, and normal cervical radiographic findings make Sandifer’s syndrome a probable diagnosis and necessitate upper gastrointestinal studies.7

Most patients have no other abnormalities. Sandifer’s syndrome is diagnosed in a relatively large number of patients with brain damage or metabolic disorders and is often interpreted as a feature of their basic disorder.1 A high prevalence of Sandifer’s syndrome was reported in the Brachman-de Lange syndrome.1 These findings may simply reflect the high prevalence of gastro-esophageal reflux disease among brain damaged children rather than a primary feature of these disorders.3

Early recognition and treatment of gastro-esophageal reflux disease in patients with Sandifer’s syndrome enhances the success of medical management, currently curative for patients with no other disorders, and contributes to improved quality of life for patients with brain damage.1,8

Is inherited thrombophilia a risk factor for arterial stroke?

The paper of Ganesan et al adds the factor V Leiden mutation to the list of inherited thrombophilias which has not been shown to be significantly increased in consecutive series of children and young adults with arterial stroke.1,2 In their commentary on this paper, Brown and Bevan1 admit ignorance as to whether the finding of inherited thrombophilia in a patient with stroke indicates an increased risk of recurrent stroke but nevertheless recommend consideration of lifelong anticoagulation. No evidence in support of this recommendation is cited.

Brown and Bevan recommend repeating measurements of protein C, protein S, and antithrombin III for at least 3 months after the acute event but depressed concentrations returning to normal between 12 and 24 months after childhood stroke have previously been reported.3-4 It would therefore seem prudent to follow concentrations of protein C and protein S for at least this time period before concluding that they can be attributed to an inherited thrombophilia, particularly if the presence of such a disorder is to be managed by “lifelong anticoagulation”.

Lyme borreliosis and intracranial aneurysms

We write the article by Oksi et al describing three patients with Borrelia burgdorferi infection and intracranial aneurysms with great interest. We encountered a patient with neuroborreliosis and an aneurysm of the basilar artery, whom we describe. A previously healthy 33 year old man presented with headache and progressive right hemiparesis. On neurological examination there was right facial weakness, moderate weakness of the right arm and leg (3/5), and brisk deep tendon reflexes. A right Babinski’s sign was present. Cerebral CT and MRI showed left anterior infarction, without enhancement with contrast. Examination of CSF disclosed 62 leukocytes/mm³; the protein content was 3.49 g/l. The IgG index was raised to 1.35. The CSF was xanthochromic, because of bilirubin. IgG antibodies against Borrelia burgdorferi in CSF were detected. A cerebral angiogram showed narrowing of the left anterior cerebral artery and an aneurysm of the basilar artery. Serum IgG antibodies against Borrelia burgdorferi were detected. Investigators in other disorders were normal. We concluded that our patient had neuroborreliosis and he was treated with ceftriaxon intravenously for 14 days. There was an almost complete recovery. The diagnosis of neuroborreliosis in this patient is supported by the clinical presentation with right hemiparesis, positive serology for Borrelia burgdorferi, the presence of IgG antibodies against Borrelia burgdorferi in the CSF, and the positive antibiotic treatment. Based on the article by Oksi et al, it is very appealing to explain what happened in our patient by using their concept. Our patient had an aneurysm of the basilar artery. If B. burgdorferi is one of the causative pathological mechanisms in neuroborreliosis, it can also lead to formation of aneurysms or vascular infarction.

However, we postulate that the presence of the aneurysm in our patient was a coincidence. There are two other explanations for the xanthochromia through bilirubin in his CSF. The first is the raised protein content of the CSF (in a patient with aseptic meningitis due to neuroborreliosis). Or, our patient had a vasculitis (supported by the pleiocytosis of the CSF and by the narrowing of the left anterior cerebral artery on angiogram) which can lead to subarachnoid haemorrhage with the presence of an aneurysm, as was shown by Chehrenama et al.5-6 A causal relation between neuroborreliosis and the aneurysm is only based on circumstantial evidence. We do not agree that the reported cases of Oksi et al support this relation. Firstly, we think that only one of the three patients had neuroborreliosis. In the other two patients there was a pleiocytosis or raised protein content in the CSF, a finding that is considered to be necessary for the diagnosis of neuroborreliosis.7-8 Also, antibodies against Borrelia burgdorferi were not detected. Besides this, no evidence exists that in the one patient with neuroborreliosis and subarachnoid haemorrhage there is a causal relation with the aneurysm. He could indeed be one of those patients who happen to have an aneurysm.

For now, the answer to the question: “Intracranial aneurysms in three patients with disseminated Lyme borreliosis: cause or chance association?” should be chance association.

JOSE D POLET
HENRI C WEINSTEIN
Department of Neurology, Saint Lucas Andreas Hospital, Amsterdam, The Netherlands

As a reply to the comments by Polet and Weinstein on our article “Intracranial aneurysms in three patients with disseminated Lyme borreliosis: cause or chance association?” we present the following comments.

Polet and Weinstein consider that only one of the three patients had neuroborreliosis. In our article we do not claim that all the patients had neuroborreliosis. However, all three patients had disseminated Lyme borreliosis based on the detection of Borrelia burgdorferi DNA in plasma samples of two patients, and an intrathecal production of antibodies against Borrelia burgdorferi in the third patient. It is also relevant to raise the question: what is neuroborreliosis? Does it require invasion of the spirochetes to none, one, or several of the following: cerebral tissue, meninges, CSF, or extraneural (or central or peripheral) nervous system. The authors state that an increased cell count or increased protein content is a necessity for neuroborreliosis, referring to the article by Garcia-Monco and Benach. However, this is not always the case as shown, for example in the studies by Lu and Coyle in which they describe patients with neuroborreliosis having DNA or antigens of Borrelia burgdorferi in CSF despite normal results of their CSF analysis and absence of antibodies against Borrelia burgdorferi in CSF.9,10

Polet and Weinstein present a case of a patient with an intracranial aneurysm and suspected neuroborreliosis. They write that antibodies against Borrelia burgdorferi were detected in the CSF. However, the total IgG was increased, and they do not state whether the antibodies were intrathecally produced or not. If we understood correctly, the authors think that they, for some reason, could associate the focal narrowing of the left anterior cerebral artery with Borrelia burgdorferi but could not do the same with narrowing of the basilar artery. They do not have any evidence that excludes the possibility that the aneurysm could also have been caused by Borrelia burgdorferi. As we refer to in our article, high numbers of inflammatory cells have been found in aneurysms.11 We consider that it is possible that the aetiology of inflammatory changes in both instances may be the same—although probably seen at a different time point. We and other authors have found that disseminated Lyme borreliosis may be associated with cerebral vasculitis.9,10

Polet and Weinstein give a straightforward answer to the question presented in the title of our article. However, we do not think it is yet possible to give an answer to this question. The previously known association of another spirochetal infection, syphilis, to aneurysm formation, indicates that there might be a causal relation between Borrelia burgdorferi infection and aneurysm formation. This possible causal relation is an hypothesis that could be tested in the future in a larger number of patients with coexisting aneurysm and Lyme borreliosis. Definite answers would require analysis of a sufficient number of aneurysm
BOOK REVIEWS

First impressions count, so it is important for a publisher to choose the right time to send a book to be reviewed. Unfortunately Butterworth-Heinemann’s timing for this book was awry. This volume arrived on my desk at the same time as I was struggling to improve a patient’s frontal lobe epilepsy. I therefore disconcerted when I could find no reference to the disease in the index under primary, orthostatic, or tremor. I turned to the book on tremor and eventually found a single inadequate sentence describing it as a clinical variant of essential tremor and a reference to clonazepam as the first line treatment. Happily, the book passed my second test—treatment options for a patient with tardive dyskinesia.

With longer acquaintance the book is more impressive. There are some good reviews and some authors have taken much trouble to produce treatment algorithms. I thought that many of the tables were excellent. A physician using the book for guidance for a patient with Parkinson’s disease, multiple system atrophy, or dystonia would find an abundance of useful information. However there are unfortunate lacunae—for example, there is no mention of the recent controversies over the use of selegilene.

A video is an excellent addition to any book on movement disorders. Unfortunately, the video refused to run on our modern video recorder at home (which never refuses offers from the Disney corporation) and ran poorly on the state of the art equipment at Addenbrooke’s Hospital. Some of the clips were of poor quality—perfectly acceptable for very rare diseases but not for common conditions. The video covered the basics well and had some particularly florid examples of tics. More cross referencing between the book and video would have helped.

Despite its limitations I would recommend this book/video combination for the groups at whom it is aimed—namely, primary care physicians and doctors in training. However, I thought that it might have been better written by a far smaller team, leaving the multidisciplinary/multiauthor approach for more advanced textbooks, which aim to become balanced views rather than the one-sidedness of this book. Overall these books and CD-ROM make an attractive package which is lost to most students and teachers as a result of the book being used for a specific Open University course. However, there is much of value in this series for those interested in the education of medical students.

JERRY BROWN

These three books and CD-ROM form part of a six book series for the Open University course on Biology: Brain and Behaviour. Book 2, Neurobiology, covers the biophysical properties of the neuron, before dealing with neural networks and the functional basis of the CNS. It is in this book that the ictal onset zone is defined. The key experimental results in a clear and concise fashion, and coupled to the well-written prose, makes the book easy to understand and follow, if somewhat verbose. Questions are thrown in throughout the text and each chapter concludes with a summary, an objectives list, and a set of questions with a few key references cited. In addition, these books were impressive in their breadth of discussion within individual topics. For example, the pain section not only covers the conventional anatomical and pharmacological aspects of nociception but also discusses a range of antinociceptive treatments and strategies. As a result the reader is left with a much more balanced view than that which is traditionally presented in its management. The book is intended to become the standard text on movement disorders currently being developed in this country. However constraints on time make it hard to commend all the details raised in these books, although the accompanying CD-ROM will be a helpful innovation in this respect. Overall these books and CD-ROM make an attractive package which is lost to most students and teachers as a result of it being used for a specific Open University course. However, there is much of value in this series for those interested in the education of medical students.

ROGER BARKER

This is a book of 172 pages dedicated to the memory of Frank Morrell. It is a multiauthor text, originating largely from North America (with a notable United Kingdom contribution from the Maudsley Hospital). After a historical review including information on recording techniques, novel approaches to using electrocorticography to predict surgical outcome after temporal lobe resection are presented convincingly and then followed by another chapter showing how parallel approaches can be applied in tailored resections. Electrocorticography findings in extratemporal epilepsy are then dealt with, confirming that restricted frontal lobe abnormalities predict a favourable outcome, particularly when combined with a well defined structural lesion. The technique of chronic electrocorticography is also reviewed, including the demonstration of long term activity and the problem of when to define the limits of interictal epileptiform activity and the ictal onset zone if a complete resection of the structural lesion is not possible. The disparate results in clinical studies using pharmacological activation are then considered, but sensible conclusions are drawn about the relatively minor role of this approach in determining the limits of a potential cortical excision, particularly when the book keeps its feet on the ground where necessary.

A comprehensive multicentre contribution follows, describing the findings in cortical dyskinesia, and the way these probably reflect the surgical outcome when compared with patients with other structural lesions. There are then three chapters on studies in the mesial temporal region, involving patient selection, prognosis, and surgical outcome. The combination of acute and chronic electrocorticography techniques. Some of this is then applied to a chapter on hemispherectomy.

The book finishes with a chapter on the applications of image guided surgery to...
The complex relations between intracranial and inner ear fluids are fascinating for both the scientist and the clinician. This volume represents the Proceedings of the Second International Conference on Intracranial and Inner Ear Fluids, which was held in Bath, UK in June 1997, and accurately reflects the sense of enthusiasm and collaboration at that meeting. The contributors include neurosurgeons, audiologists, otologists, neurologists, epidemiologists and basic scientists, and the scope of the material is very impressive.

The book comprises four sections. The first, **intracranial physiology**, contains four chapters including a very clear review of the anatomy and physiology of intracranial fluids by Segal, and then three examples of experimental work on cats, guinea pigs, and humans. The second section, **intracranial pathophysiology**, opens with a review of “Pathophysiology of the cerebrospinal and cerebrovascular circulations” by Pickard et al, and then eight chapters considering related topics. The tympanic membrane displacement (TMD) test procedure is discussed, representing a non-invasive method of assessing intracranial fluid pressure, and particularly useful in the assessment of shunt malfunction. The third section, **inner ear physiology**, contains 10 chapters, and considers the inner ear fluids, perilymph, and endolymph in very considerable detail. The final section, **inner ear pathophysiology**, is perhaps the least consistent in the volume and at times strays from the fluid remit of the book. It does, however, contain a very useful chapter considering the Tullio phenomenon (by O’Mahoney and Luxon) that deserves careful study.

For anyone interested in the areas described above this book will be interesting and useful. Collaboration and indeed communication between those interested in the intracranial fluids and inner ear fluid is in its infancy, and whereas this book does contain exciting material there is little that is of clinical relevance yet, although some of the techniques and concepts described hold great promise. Many departmental libraries would benefit from the inclusion of this volume, although only those directly involved in this area would be able to justify a private purchase.

**DAVID BAGULEY**

No one can doubt the increasing importance, to affected families and the healthcare system, of Alzheimer’s disease, Parkinson’s disease, and the other degenerative conditions of the nervous system. Furthermore, study of the degenerating brain can provide fundamental insights into brain function. Although there are authoritative books on memory, on disorders of memory, and on the neurological diseases covered in this book, the strength of the book is in the accounts of different views of memory in neurodegenerative disease. These differing perspectives mean that this book will be of interest to neurologists, neuropsychologists, psychiatrists, and researchers in the neurosciences.

The book is divided into three broad sections with summary chapters at the end of each. The first section deals with the biological aspects of neurodegenerative disease, with reviews on neuropathology, animal models, neurochemistry, and neuroimaging.

The two chapters on neuroimaging are particularly valuable, being clear and well referenced. Although the genetic advances in this area are mentioned in several chapters, it is not a major topic in this work.

The second section reviews the different cognitive aspects and explores the role of neurodegenerative conditions in the understanding of organisation of memory. Executive functions in both subcortical and cortical dementia syndromes, episodic and semantic memory, and non-declarative memory are systematically covered. The discussion of disintegration of distinct memory systems in different degenerative conditions will be of interest to psychologists and doctors alike, although this section will be of special interest to neuropsychologists.

The last section of this book will be particularly useful for clinicians, as there are admirable summaries of the assessment of memory, including very interesting accounts of cross cultural issues in neuropsychological assessment and the reliability of psychometric instruments. The important clinical issues of early detection and of differentiating dementias and memory disorders are well presented. This section ends with an exploration of drug and surgical treatments for neurodegenerative disease.

There is particular consideration of the possible cognitive sequelae of neurosurgery for akinetic-rigid syndromes and tremor. I would recommend this book to anyone who wants a clear and authoritative account of the role of neuropsychology, experimental psychology, and theories of memory structure and organisation in relation to the neurobiology of the dementias and other neurodegenerative conditions.
