Perforating branches from offending arteries in hemifacial spasm: anatomical correlation with vertebrobasilar configuration

Tetsuya Nagatani, Suguru Inao, Yoshio Suzuki, Jun Yoshida

Abstract

Objective—In microvascular decompression for hemifacial spasm, the perforating branches around the facial nerve root exit zone occasionally complicate facial nerve decompression. In this context, the vertebrobasilar configuration was retrospectively correlated with the perforating branches.

Methods—Based on vertebral angiography, magnetic resonance angiography, and three dimensional computed tomographic angiography, 69 patients were divided into three groups, according to the anatomy of the vertebrobasilar system. In patients with the type I configuration, the vertebral artery on the affected side was dominant and had a sigmoidal course. The type II patients had the basilar artery curving mainly towards the affected side. The type III patients showed the basilar artery either running straight or curving toward the unaffected side. The relation of the anatomical configuration of these vessels with the perforating branches around the facial nerve exit zone was investigated.

Results—The posterior inferior cerebellar artery in type I patients (n=33) and the anterior inferior cerebellar artery in type II (n=5) and type III (n=31) patients were the most common offending arteries. More than half of the type I patients (n=20) showed no perforating branches around the facial nerve exit zone. However, the type II (n=3) and III patients (n=23) often showed one or more perforating branches around that region.

Conclusions—The configuration of the vertebrobasilar system has a significant correlation with the presence of perforating branches near the site of microvascular decompression. These perforating vessels are often responsible for the difficulty encountered in mobilising the offending artery during the procedure.

Keywords: hemifacial spasm; microvascular decompression; vertebrobasilar; perforating branch

Gardner and Sava are credited with the first published report of five patients with hemifacial spasm, who were successfully treated by placing a piece of prosthetic material between the internal auditory artery and the cochlear nerve. Jannetta et al subsequently showed that the arterial compression of the facial nerve root exit zone was responsible for the facial spasm and standardised the technique of microvascular decompression. Although several therapeutic alternatives have been reported, microvascular decompression is widely accepted as the most effective and safe treatment for hemifacial spasm. Some potential difficulties, however, exist with this technique. Occasionally, surgeons have had to manipulate the small perforating branches around the root exit zone. This, however, can interfere with the mobilisation of the compressing vessels and the creation of space for the placement of the prosthetic materials without damage to the surrounding structures. Some authors have attempted to detect the offending vessels in radiological studies, but there are no reports available regarding the perforating branches around the root exit zone of the VIIth nerve. In this study, we have focused on the configuration of the vertebrobasilar system as seen on the preoperative imaging as a guide to the detection of the perforating branches encountered during microvascular decompression for hemifacial spasm.

Patients and methods

Seventy seven consecutive patients with hemifacial spasm were treated at our institution between July 1983 and April 1996. Sixty nine of these patients underwent microvascular decompression after angiography, magnetic resonance angiography (MRA), or three dimensional computed tomographic angiography (3-D CT angiography). The 69 operations for microvascular decompression, including three reoperations, were performed on 26 men and 43 women, with ages ranging from 24 to 72 years (mean age 50.6 years). In 36 patients, facial spasm was found on the right side; in 33, it occurred on the left. No patient had bilateral manifestations. The hemifacial spasm was diagnosed by careful study of history and complemented by radiological imaging to rule out other aetologies which may be responsible for spasm such as other vascular diseases or a mass lesion in the posterior fossa.

The operative procedure was similar to that previously described by Jannetta et al. We applied a piece of muscle as prosthesis until 1986. Since then, we have been using Teflon-cotton, although other materials have been recommended as prostheses.

The relation between the microvascular structures including the perforating branches and the facial nerve was confirmed by reviewing operative notes or videos. The preoperative
duration of the symptoms ranged from 3 months to 16.7 years, with a mean duration of 73.7 months. We categorised the operative results at discharge as complete relief, partial relief, or no benefit. The imaging demonstrated that the vertebrobasilar anatomy followed one of three characteristic patterns. In the type I configuration, the vertebral artery ipsilateral to the spasm was dominant and sigmoidal in course. In type II, the vertebral artery contralateral to the spasm was dominant with the basilar artery deviated from the midline and curving mainly toward the affected side; in type III, the basilar artery remained near the midline or curved towards the unaffected side. The three types are shown in a schematic diagram in fig 1. The compressing vessels and their perforating branches arising from the offending arteries were examined by reviewing the operative notes and divided into two groups according to the existence of the perforating branches around the compressing site. In each type of the vertebrobasilar configuration, the offending artery causing the hemifacial spasm and the presence or absence of the perforating vessels were also examined.

As a control group, we also included 62 patients (male: female ratio 25:37; age range 24–74 years; mean age 67.8 years) who had undergone either angiography, MR angiography, or 3-D CT angiography for some other condition to compare the radiological features of the vertebrobasilar configurations between patients with or without hemifacial spasm. As the control group did not have hemifacial spasm, it was difficult to categorise them into type I and type II patients. Therefore, the control group was divided into two classes: (1) the patients having a tortuous vertebrobasilar system; (2) the patients with a non-tortuous vertebrobasilar system. To maintain similarity and enable a statistical comparison between patients having hemifacial spasm and the control patients, the type I and type II patients in the hemifacial spasm group were also combined into the category of “tortuous type”.

Results
The surgical treatment resulted in a complete relief in 55 patients (80%) at the time of discharge, and in partial recovery in 14 patients (20%). No patient was placed in the category of “no response”. There was no operative mortality in the series. According to the vascular imaging, the 69 operated cases included 33 (47.8%) patients of type I, five (7.2%) of type II, and 31 of (45%) type III. There was no significant difference in the sex, age, or the surgical result among the three types. The identity of the offending vessels in cases of each anatomical group is summarised in table 1. The posterior inferior cerebellar artery (PICA)
was the most common offending vessel in type I (73%), and the anterior inferior cerebellar artery (AICA), in both types II and III (100% and 81% respectively). Table 2 summarises the number of the patients having perforating branches near the root entry zone of the VIIth nerve in each type. Twenty patients of the type I group showed no perforating branches whereas 12 patients showed perforating branches; and two of the type II group showed no perforating branches whereas three showed perforating branches; eight of the type III group had no perforating branches whereas 23 patients had them. The perforating branches tended to be more frequent in the AICA than in the PICA; however, the difference was not statistically significant (table 3). The control group consisted of 21 patients in the tortuous type (34%) and 41 in the non-tortuous type (64%). Table 4 shows that the difference in the ratio between the control group and the hemifacial spasm group reaches significance even though the mean age in the first group was 67.8 years compared with 50.6 in the second group.

ILLUSTRATIVE CASE

A 50 year old man presented with a right sided hemifacial spasm. The preoperative 3D CT angiography showed a rather straight vertebrobasilar configuration which could be categorised into type III (fig 2A). During surgery, we confirmed that the AICA was the offending artery and that it had two perforating branches penetrating the brain stem near the root exit zone. This significantly increased the difficulty in dissection to create an adequate space between the compressing vessel and the root entry zone (fig 2B).

Discussion

GENERAL ASPECTS

Hemifacial spasm is a syndrome that is spontaneous and gradual in onset and is characterised by intermittent twitching of the muscles of facial expression on one side of the face. Twitching typically begins about the eye and later spreads to involve the other muscles innervated by that facial nerve.3 In some patients, however, twitching begins in the buc-
vascular muscles and progresses over the face, a subtype described as an atypical hemifacial spasm. Our series included no cases of the atypical form. Although several aetiology hypotheses have been proposed for hemifacial spasm, it is now widely accepted that it arises primarily from compression of the facial nerve at the root exit zone of the pons, usually by an adjacent artery. The arteries involved in the typical hemifacial spasm include the PICA (22.9–59%), the AICA (17–39%), and vertebral artery (3.6–18%). We found a similar incidence of the offending arteries in the present study.

ANATOMICAL EVIDENCE
Kondo et al delineated two characteristic configurations of the vertebrobasilar system in hemifacial spasm. In the first type, a tortuous vertebral artery on the affected side is often larger than the contralateral vertebral artery and gives rise to a redundant and dilated PICA. In the second type, an S shaped basilar artery deviates from the midline and a tortuous AICA arising from it courses toward the internal auditory meatus on the affected side. In this category, usually the PICA is aplastic or hypoplastic. The first corresponds to type I and the second to the type II group of our series. We noted another characteristic configuration—that is, a normal vertebrobasilar system—and defined it as type III. This group comprised half of the total patients in our series. Among the offending vessels, the PICA was the most common compressing vessel in type I and the AICA in types II and III groups. Thus there was a significant difference between the type I and type III groups with regard to the offending vessels. On the other hand, Matsushima et al in a necropsy study examined 35 sides of the brain from 20 patients without hemifacial spasm and showed that in up to 70% of specimens, arterial attachment at the root entry zone was evident. They stated that the attachment was light and so did not manifest clinically as hemifacial spasm. Nearly half of our patients in the study as well as most of our patients in the control group had a non-tortuous vertebrobasilar artery and were categorised as type III patients. It is possible that there may be an attachment of the offending vessel to the VIIth nerve in our type III patients with hemifacial spasm similar to that seen in the series of normal patients by Matsushima et al, that became manifest. This group reported that the contacting vessels included the AICA in 24 patients, the PICA in two, and the vertebral artery in three. In our series, the finding that the AICA is the most common offending vessel in the group III patients is, therefore, consistent with their findings.

With regard to the perforating branches arising from the AICA and the PICA, Shrontz et al reported a unique study. They investigated the characteristics of the perforating branches in the posterior fossa using cadaveric dissection and ascertained the number of vessels, their origins, and their diameters to determine the best locations for anastomosis. According to this study, the PICA gives off only one or two perforating branches from the proximal 15 mm segment in the cisternal portion, but more branches arise from the distal cisternal portion. As the AICA extends from the basilar artery in a lateral and caudal direction, perforating branches are most concentrated at the distal portion of the bifurcation of the metatal and hemispheric branches where the compression point usually exists. Matsushima et al also showed that in most of the patients, this part of the vessel is the portion causing the compression. These findings lead to the conclusion that in patients with hemifacial spasm with a normal vertebrobasilar system, some perforating branches from the AICA around the compressing point exist. However, the PICA is likely to give off perforating branches because it acts as an offending artery compressing the facial nerve root entry zone at the proximal cisternal portion in patients with a tortuous vertebral artery and in this portion of the PICA, usually the number of perforators is small. Our results were compatible with these conclusions (table 2). In the region of the root entry zone of the VIIth nerve, the AICA had more perforating branches than the PICA, but no significant difference was found (table 3).

In summary, the possibilities of encountering perforating branches while performing microvascular decompression for hemifacial spasm will increase as the vertebrobasilar configuration gets nearly normal.

We have presented the detailed findings from a 50 year old man with a right hemifacial spasm. The preoperative 3D CT angiography had shown a vertebrobasilar configuration curving to the unaffected side which could be categorised into the type III subgroup (fig 2A). At surgery, we confirmed that the AICA was the offending artery and that it had two perforating branches penetrating the brain stem near the root exit zone. This rendered the dissection to create adequate space between the compressing vessel and root entry zone extremely difficult (fig 2B).

The imaging information does not always predict the exact site of compression of the facial nerve. Some authors maintain that angiograms do not have a significant value in the management of hemifacial spasm. Since 1992, we have used a preoperative MRA or 3D CT angiography to exclude the existence of other vascular lesions. The purpose of our present study and our classification of the vertebrobasilar anatomy is not to identify the compressing artery but to attempt to correlate the configurations of the vertebrobasilar system with the perforating branches that are encountered during surgery for hemifacial spasm. Thus the radiological imaging will be helpful in identifying the patients in whom perforating branches will be encountered during microvascular decompression for hemifacial spasm, leading to a difficult dissection.

Conclusion
We retrospectively investigated 69 cases of hemifacial spasm, attempting to correlate the configuration of the vertebrobasilar system...
with the existence of short perforating branches near the root entry zone of the VII nerve. It is concluded that a symmetric, non-tortuous vertebrobasilar system is more likely to give rise to short perforating branches, which may cause difficulties during microvascular decompression.
