Magnetic resonance imaging and vertebral artery dissection

Since the advent of advanced radiological modalities such as MRI and magnetic resonance angiography (MRA), dissections of cervical arteries are increasingly recognised as a common cause of stroke in young adults. Auer et al. recently advocated MRA as the initial diagnostic tool for vertebral artery dissection. Conventional angiography might be avoided altogether in subjects with a suspicious history and MRA images suggestive of a dissection (double lumen or mural haematoma). The sensitivity of MRA for the diagnosis of vertebral artery dissection was considerably better in the hands of Auer et al., but in this study the specificity (true negative rate in subjects free of disease) was not considered because all patients had vertebral artery dissection. The following case report illustrates that care must be taken to avoid false positive results when using MRA for the diagnosis of vertebral artery dissection.

A 47 year old male pilot suddenly experienced clumsiness and slight loss of strength in the right arm and leg during a long distance flight, while he stooped forward. During the following hours, he developed a global headache without irradiation to the neck, but the other symptoms gradually diminished. Prior history was unremarkable, except for a 3 hour period of horizontal diplopia which suddenly developed 3 months earlier. He had never smoked. Family history was negative for cardiovascular disorders. The patient later confessed that he had recently picked up the habit of gargling his throat with toothpaste twice a day, always with his neck in extreme retroflexion.

General physical examination (8 hours after onset of symptoms) was normal. Neurological examination showed minimal paresis and impaired dexterity of the right hand, mild circumduction of the right leg, and an insecure tandem gait. An MRI (including T1 weighted spin echo images with and without fat suppression, and proton density and T2 weighted fast spin echo sequences, performed on a 1.5 Tesla whole body MRI system) performed several hours later visualised both a fresh and an old right sided cerebellar infarct (figure A). In addition, MRI showed an irregular right vertebral artery in which a patent lumen was partially surrounded by a semi-lunar area of high signal intensity on T1 and T2 weighted images. On fat suppressed images, this area’s high signal intensity persisted, excluding the possibility that it originated from perivascular fat. This image was suggestive of mural haematoma due to vertebral dissection (figure B). Because we were reluctant to base any treatment decisions (anticoagulants) merely on MRI findings, digital subtraction angiography was performed on the day of admission. This examination was normal (figure C). Shortly after this procedure, the patient developed vertigo and nystagmus which disappeared after 3 hours. Because we were puzzled by the discrepant findings on conventional angiography and MRI, we performed an MRA 4 days later. At this examination, the semi-lunar area of high signal intensity was found again (figure D), despite saturation of craniofugal and craniopetal flow respectively, which was applied to exclude the possibility that the high signal originated from flow in the periarterial venous plexus. Therefore, this examination was again suggestive of right vertebral artery dissection. An extensive search for other causes of stroke showed no abnormalities. Hence, due to the continuing discrepancy between conventional angiography and MRI/MRA, and due to the absence of any other cause of stroke, no certain diagnosis could be established.

In this patient, a diagnosis of right vertebral artery dissection was initially made given the clinical course with repeated episodes of ischaemia restricted to the vertebrobasilar system, as well as the suggestive MRI findings. We speculated that habitual gargling was a potential underlying cause, as neck retroflexion can cause cervical dissections. However, we had to reject this diagnosis in view of the normal conventional angiography, which remains the gold standard for diagnosing cervical artery dissection. In one series, conventional angiography was never falsely negative in patients with clinical signs or symptoms of vertebral artery dissection. The possibility that conventional angiography had nevertheless yielded a false negative result seems highly unlikely. In dissected arteries, MRI/MRA can detect intimal flaps, mural haematomas, or aneurysmal dilatations that are sometimes missed by conventional angiography, but even in such patients, conventional angiography is never completely normal in the acute stage. Follow up examinations of patients with proven vertebral artery dissection indicate that the appearance of a dissected artery on conventional angiography can normalise in a substantial proportion of patients, but always after an interval of at least 1 to (usually) several weeks. Conventional angiography in our patient was performed on the day of admis-
In this case report, we describe a patient with CPEM in whom extrapontine myelinolysis was considered. A repeat MRI 12 days after the onset of symptoms showed high signal intensity within the pons suggestive of CPEM. A strong index of suspicion for CPEM was considered. Admission MRI, EEG, and spinal fluid examination were normal. On admission she had a sodium concentration of 105 meq/l. An infusion of 3% saline at a rate of 150 ml/hour was given during 6 hours. Ten hours later her sodium was 134 meq/l and she was mute and tetraparetic. She seemed catatonic with motor perseveration. Transfer to our hospital was requested.

On admission her vital signs were normal. She was mute without any spontaneous volitional movements except for visual pursuit. She was tetraparetic and hyperreflexic with increased tone and bilateral Babinski’s signs. CPEM was suspected. Admission MRI, EEG, and spinal fluid examination were normal. Over the next 2 days the reflexes normalised and the Babinski’s signs disappeared but she continued to have mild diffuse weakness. She had waxy flexibility and assumed bizarre non-physiological postures consistent with catatonia. Psychogenic unresponsiveness was suspected and she was started on risperidone and sertraline. There was no benefit. Electroconvulsive therapy was proposed by a psychiatry consultant but was refused by the patient’s family. The clinical picture was dominated by an akinetic mutism with marked catatonia. Catatonia due to CPEM was considered. A repeat MRI 12 days after the onset of symptoms showed high signal intensity areas in the pons, caudate, and putamen consistent with CPEM. It has been suggested that saturation slabs in conjunction with MRA completely suppress flow related high signal, thus distinguishing it from high signal from an intramural haematoma which cannot be suppressed by saturation slabs.

The second tissue that may falsely present as a dissection is fat that directly surrounds vertebral arteries, turbulence and magnetic susceptibility near sharp vessel turns can also cause false positive MRA results. In some patients, MRI cannot distinguish between intramural haematoma and intramural haematoma, leading to false conclusions.

Decisions based on false positive MRI/MRA results can be hazardous due to the sometimes severe side effects of anticoagulants, the treatment that is recommended by some to prevent further ischaemic events. Another danger of a false positive diagnosis of vertebral dissection is that it may preclude the search for other causes of stroke that could be amenable to secondary prevention.

MRI/MRA remains important because it helps visualise ischaemic lesions and, in some patients, provides complementary morphological information to cerebral angiography. Furthermore, it is a non-invasive procedure, an important advantage over cerebral angiography which carries a morbidity and mortality risk. Our patient, who developed transient neurological deficits shortly after angiography, underscores this. Therefore, MRA can play a part in the diagnosis of vertebral artery dissection, provided that the pitfalls mentioned above are recognised to avoid false positive results. In case of doubt, cerebral angiography remains the gold standard for vertebral artery dissection.

Catatonia due to central pontine and extrapontine myelinolysis: case report

Central pontine and extrapontine myelinolysis (CPEM) are recognised complications of hyponaemotrauma and its overly rapid correction. CPEM usually presents with spastic tetraparesis and pseudobulbar palsy. We describe a patient with CPEM in whom behavioural manifestations overshadowed corticospinal tract signs.

A 64 year old Chinese speaking woman presented with a history of episodic psychotic depressive syndrome for one year and MRA/MRI exam showed high signal intensity originated from a plexus suggestive of extracranial vertebral artery dissection. Two anatomical structures surrounding vertebral arteries contribute to these problems. The first structure is the venous plexus that surrounds vertebral arteries. This structure may have a semilunar appearance, and slow flow in its lumen may be due to extremely slow flow. The second structure is fat that directly surrounds vertebral arteries, turbulence and magnetic susceptibility near sharp vessel turns can also cause false positive MRA results.
Association between butyrylcholinesterase K variant and the Alzheimer type neuropathological changes in apolipoprotein E 4 carriers older than 75 years

Apolipoprotein E (ApoE) 4 has a strong influence on the development of sporadic Alzheimer's disease in many ethnic populations. However, ApoE 4 is neither necessary nor sufficient for the development of Alzheimer's disease, suggesting that other genes increase the risk of Alzheimer's disease. One such new candidate is the butyrylcholinesterase (BCHE) gene (BCHE). 1 BCHE is associated with senile plaques (SPs) and neurofibrillary tangles (NFTs). Lehmann et al reported that the K variant of BCHE (BCHE-K) was associated with the development of Alzheimer's disease, especially in ApoE 4 carriers older than 75 years. 1 A possible mechanism as to how BCHE-K is related to Alzheimer's disease under the influence of ApoE 4 is the acceleration of Alzheimer type neuropathological changes. If BCHE-K has an effect on the development of Alzheimer's disease in ApoE 4 carriers, the formation of Alzheimer type neuropathological changes may be accelerated by BCHE-K in the ApoE 4 carriers.

We have examined genotypes of BCHE and ApoE, and densities of the senile plaques (SPs), dystrophic neurites (NPs), and neurofibrillary tangles (NFTs) in the brains from 91 patients with Alzheimer's disease and 90 non-demented subjects from a postmortem series of Japanese. Clinical and postmortem diagnosis of Alzheimer's disease was carried out as described previously.2 The densities of Alzheimer type neuropathological changes were quantified by averaging the counts of those in the hippocampus and superior temporal gyrus. Genotypes of BCHE and ApoE in all patients were determined as described elsewhere. 1 Genotypic and allelic distributions of BCHE were analysed by chi squared test. The densities of the SPs, NPs, and NFTs, and ages at onset and durations of illness were compared among BCHE genotypes with the Kruskal-Wallis test or Mann-Whitney U test in total subjects, those with Alzheimer's disease, and non-demented subjects. We also examined these relations in the subgroups divided by the ApoE 4 status or the age of 75 years. Statistical significance was defined as two tailed probabilities of <0.05.

There were no significant differences in the frequency of BCHE-K genotypes or alleles between patients with Alzheimer's disease (0.16 in allele frequency) and non-demented subjects (0.18), and in the total subjects, ApoE 4 carriers or non-ApoE 4 carriers, although a strong association of ApoE 4 alleles with Alzheimer's disease was found in this population (p=0.004). Genetic association of BCHE-K genotypes with sporadic Alzheimer's disease was non-significant in all subjects older than 75 years, the ApoE 4 carriers older than 75 years, and non-ApoE 4 carriers older than 75 years. There was no genetic association of BCHE-K with the densities of the SPs, NPs, or NFTs in the hippocampus and superior temporal gyrus in the total subjects, in the Alzheimer's disease, or non-demented groups, or with ages at onset or duration of illness in Alzheimer's disease. However, when we divided total subjects into two subgroups with different ApoE 4 status, there was significant association between BCHE-K and the density of the SPs and NPs in the superior temporal gyrus (STG) in the ApoE 4 carriers (SPs, p=0.04; NPs, p=0.03; data not shown). Furthermore, we analysed the correlation between BCHE-K and the densities of the SPs, NPs, and NFTs in the hippocampus and superior temporal gyrus in the ApoE 4 carriers older than 75 years and non-ApoE 4 carriers older than 75 years. A similar trend was seen in the hippocampus and superior temporal gyrus in the ApoE 4 carriers and non-ApoE 4 carriers over 75 years (n=95). The frequency of BCHE-K in our study was 0.18. This was not significantly different from that in the British population examined by Russ et al (0.20). However, the frequency of BCHE-K in our study was 0.18. This was not significantly different from that in the British population examined by Russ et al (0.20). However, the frequency of BCHE-K in the British control population reported by Lehmann et al was 0.09, which was significantly lower than our results (p=0.04). These findings indicate that the frequency of BCHE-K is not in agreement with the development of Alzheimer's disease would be different among sample populations.

Our neuropathological study disclosed a significant association of BCHE-K with Alzheimer type neuropathological changes in the ApoE 4 carriers older than 75 years, but not in the non-ApoE 4 carriers. Lehmann et al showed that BCHE-K was strongly associated with the development of Alzheimer's disease in the ApoE 4 carriers older than 75 years.3 Analyses of the same subgroup of ApoE 4 carriers older than 75 years increased statistical significance in both our studies and that of Lehmann et al. This suggests that BCHE-K as a genetic marker is linked with formation of Alzheimer type neuropathological changes or development of Alzheimer's disease in the ApoE 4 carriers older than 75 years. However, a decrease of the severity of Alzheimer type neuropathological changes with BCHE-K in our study was not expected because Lehmann et al showed an increase in frequency of the BCHE-K allele in Alzheimer's disease.4 Singleton et al also reported that BCHE-K was not associated with the densities of the SPs and NFTs, even in the ApoE 4 carriers.5 In addition, BCHE-K was not related to the development of Alzheimer's disease in the ApoE 4 carriers in our study. Russ et al6 and Singleton et al also showed a lack of association between BCHE-K and the development of Alzheimer's disease. However, Hiltunen et al showed that BCHE-K had a protective effect on the development of Alzheimer's disease in ApoE 4 carriers younger than 75 years.7 The effects of BCHE-K on the Alzheimer type neuropathological changes or development of Alzheimer's disease are different among studies, suggesting that the significant genetic association in the studies by Lehmann et al, Hiltunen et al, and ourselves might be linked disequilibrium with relevant variability in BCHE or other adjacent gene on chromosome 19, and that BCHE-K does not play a direct part in the pathogenesis of Alzheimer's disease.

Idiomotor prosodic apraxia

Prosody is a non-verbal or suprasegmental feature of language that conveys various levels of information to the listener, including linguistic, affective (attitudinal and emotional), dialectical, and idiosyncratic data. The acoustical features underlying prosody include intonation, melody, loudness, stress, accent, and pauses. These acoustical features are typically spared in patients with cortical dementia such as Alzheimer’s disease in which temporoparietal cortices are primarily affected. Patients with Alzheimer’s disease, however, often develop apraxia, which can be defined as a disorder of skilled movement not caused by weakness, ataxia, deafferentation, abnormal tone or posture, movement disorders (such as tremor or chorea), intellectual deterioration, poor comprehension, or uncooperativeness. Moreover, subtypes of apraxia have been delineated and are defined as follows: ideational apraxia and apraxia of speech. The patient was a 71-year-old, retired physician with a 3 to 4 year history of memory impairment. Neuropsychological evaluation disclosed a high average to superior general intellectual functioning, with mild impairment in naming to confrontation and episodic memory for visual memory. His visuospatial ability remained relatively unimpaired and was rated as average for his age. His comprehension for verbal and written instruction was intact. At the present time he is still well oriented to time and place, and is somewhat independent in activities of daily living. He is, remarkably, not depressed, but does, repeatedly, raise concern regarding the person to whom he has become to his wife.” Moreover, mild hypoperfusion in the frontaltemporal lobes bilaterally was seen on SPECT investigation and no evidence of pathognomonic laboratory results were found. Taken together, the pattern of episodic memory and naming impairments and functional imaging findings was thought to be consistent with the early stages of dementia of the Alzheimer’s type (DAT) in keeping with National Institute of Neurological and Communicative Disorders Association-Alzheimer’s Disease and Related Disorders Association criteria. The patient was subsequently referred to our department for “prospective memory book training” and the following assessments and follow up assessments to index progression of disease.

During our sessions his wife had stated that the patient could no longer “act.” The patient complained that her once “flamboyant and ‘unblushing’ husband could no longer “put any feeling into his lines” when they read play scripts together. He thought that he had “lost his enthusiasm to act” consequent to his new found memory loss and an “understandable depressive reaction.” It became clear, however, that the patient was remarkably not depressed and that he maintained normal prosodic speech during conversation. When asked to use prosody to command when reading script, however, this once gallant actor spoke without melody, loudness, stress, or accent, with appropriate pauses. To quantify this patient’s peculiar deficit, the patient was required to read and repeat words and sentences to prosodic command and imitation (table). For example, the patient was told to read the words “Honey PLEASE!!” with loudness, stress, accentuation of the word “please,” and as if he really meant it. If he failed (the words were read without the acoustical features expected), the patient was asked to imitate the experimenter’s reading of the word(s) or sentence which incorporated the appropriate prosodic elements only after he was asked to describe the affective prosodic quality of the phrase to ensure good comprehension. Five age-matched normal healthy controls volunteered to read the items found in the table, and in each case, read spontaneously the word or phrase with appropriate and expected prosody. The patient was unable to read any words or sentences with normal (appropriate and expected) prosody. Indeed, the patient had lost his ability to “act.” The patient’s use of prosody did, however, improve dramatically with imitation. That is, he was able to repeat eight of the 10 items in the table with appropriate and expected prosody. Interestingly, the single item that he continued to have trouble producing was item three (You know...there was a time when...). And as if not after pause after the words “you know” suggesting that this patient seems to also have features characteristic of motor apraxia. Hence, because he had available the knowledge to successfully “act” and use appropriate prosody, but failed to produce prosodic speech to command, dysfunction of the praxis production system is implied rather than the conceptual system. Thus, ideomotor prosodic apraxia can be defined as an inability to produce prosody to command during speech. The precise underlying mechanism(s) responsible for producing this deficit is unknown, although Heilman et al and Tucker et al have hypothesised that the right hemisphere is indeed dominant for organising the affective-prosodic components of language and gestural behaviour and that the functional neurological architecture of affective language in the right hemisphere was analogous to the organisation of propositional language in the left (non-dominant) hemisphere. Conceptually, therefore, evidence of poor affective prosody to command and spontaneous affective prosody, and good affective prosodic repetition and comprehension would suggest a “transcortical aphasias.” Note however, that the patient’s spontaneous prosody was unaffected whereas spontaneous speech is affected by a transcortical motor aphasia. Hence, we might place the critical lesion for prosodic apraxia in the left dorsolateral frontal lobe, extending into the deep frontal
The clinical features, including the vocal cord findings, are summarised in the table. VCAP was present in five of the seven patients with SCA1. Although it is difficult to know when the VCAP first became manifest in each patient, patient 1 showed VCAP confirmed by laryngofibroscopy only 2 years after the onset of gait disturbance. All five patients with VCAP showed mild dysphagia requiring no tube feeding, and four patients had a history of stridor at night. Patient 1 showed VCAP accompanying dysphagia without stridor at night even in an early stage of the disease. The VCAP was found to be severe on laryngofibroscopy in two patients with breathing difficulty on inspiration. Patient 5, who had the severest VCAP, developed stridor during wakefulness in all patients. In patients 4 and 5, the breathing difficulty on inspiration was improved by tracheostomy. The respiratory flow volume study did not detect abnormality in patient 2.

The CAG repeat number tended to be higher in the patients with VCAP than in the patients without VCAP (p=0.05), but the duration of illness was not significantly correlated with the presence of VCAP (p=0.43). This is the first report that VCAP is often associated with SCA1. As VCAP may not usually be a late feature in patients with SCA1, evaluation of VCAP is necessary even in early stages of the disease. It is not surprising to find VCAP in patients with stridor, because stridor is usually caused by airway obstruction of the larynx. However, VCAP was detected by laryngofibroscopy in a patient without stridor who had dysphagia. Furthermore, all patients with VCAP exhibited dysphagia. We therefore think that laryngofibroscopy should be performed in SCA1 patients with dysphagia as well as stridor.

The mechanism of VCAP may be divided into some types, the paralytic type, the non-paralytic type, and these two combined type. The first is possibly caused by loss of neurons in the nucleus ambiguus. The second is considered to be due to over-activity of the intrinsic laryngeal muscles. Stridor due to paralysis has been found to be more prominent in sleep than during wakefulness; whereas stridor by non-paralytic dysfunction has been found both during the daytime and during sleep. We suspect that the VCAP in patients with SCA1 may be dominantly paralytic, because the nucleus ambiguus is sometimes pathologically involved in SCA1 and because stridor in our patients with SCA1 was more marked in sleep.

Our laryngofibroscopic findings suggested that severe VCAP caused breathing difficulty on inspiration in the patients with SCA1 by obstructing the airway. Moreover, the stridor during wakefulness as well as sleep indicated it to be very serious. The important question concerns when tracheostomy should be carried out after the diagnosis of VCAP to prevent respiratory abnormalities leading to sudden death. Although we consider tracheostomy at the stage when breathing difficulty on inspiration or stridor during wakefulness is noted, it awaits further study with a large number of patients to decide which stage is best for tracheostomy.

Furthermore, we now consider endoscopic cord lateralisation as another possible management for VCAP.

Vocal cord abductor paralysis in spinocerebellar ataxia type I

Vocal cord abductor paralysis (VCAP) is considered a sign of a poor prognosis in neurodegenerative diseases, because severe laryngeal dysfunction by VCAP may result in acute airway obstruction and require emergency tracheostomy. Although VCAP is a cardinal feature in multiple system atrophy (MSA), it has not been reported in several types of spinocerebellar ataxias with dominant inheritance. We evaluated the movements of the vocal cords of seven patients with SCA1 by laryngofibroscopy.

Seven unrelated patients with SCA1 who had had confirmed CAG repeat of ataxin-1 were investigated. There were two men and five women ranging in age from 27 to 67 years old (mean 44.5 years). Spouses and other family members, in addition to the patients, were questioned about events of stridor, dysphagia, and dysphonia. Vocal cord movement was examined by laryngofibroscopy and recorded during inspiration and phonation.

The grading scale used to evaluate maximal abduction of the vocal cords during laryngofibroscopy was as follows: (+)=normal; (+)=median position; (++)=paramidline position; (+++)=midline position. For the evaluation of VCAP, we tried the respiratory flow volume loop study as well in one patient (patient 2) in whom maximal abduction of the vocal cords was slightly limited (+) on laryngofibroscopy.

The correlations between VCAP and CAG repeat length or duration of illness were analysed by the non-parametric Mann-Whitney U test.

Brief summary of the clinical features and CAG repeat numbers in the patients with SCA1

Lateral gaze synkinesis on downward saccade attempts with paramedian thalamic and midbrain infarct

The symptoms of paramedian thalamic and midbrain infarct include ocular motor disturbances mainly in the vertical plane. We here describe a patient with the additional feature of an unusual horizontal eye movement synkinesis.

A 60 year old overweight man, with diabetes and mild hypertension, suddenly fell into a coma that lasted for 4 hours and was followed by slight right hemiparesis, recent memory impairment, hypersomnia, and vertical gaze impairment.

On admission to our centre, about 10 days after symptom onset, the patient still presented fluctuating drowsiness from which he could be easily aroused, normal cognitive functions with mild attention disturbance, slight right facial weakness, and mild incoordination at the finger-to-nose test with his right arm.

The most important findings involved ocular motor function. Both pupils were normal in diameter and reacted normally both to light and to convergence. The cover test did not disclose any eye misalignment. During attempted fixation, the patient showed saccade oscillations (usually square and macrosquare wave jerks)—that is, back to back involuntary horizontal saccades with an amplitude ranging from about 2 to about 10 degrees and with an intersaccadic interval of about 200 ms, that brought the eyes away from and back to the fixation point, at an approximate rate of three every 2 seconds. Clinical examination of eye movements in the horizontal plane and visually guided reflexive saccades recorded by the infrared reflection technique were both normal, whereas the amplitude range of vertical saccade and smooth pursuit eye movements covered only a few degrees of upward gaze.

Vertical amplitude range was slightly greater for the vestibulococular reflex in the pitch (yes–yes) plane. Moreover, when the patient attempted to make a downward saccade, he showed a gaze deviation to the left (figure). This synkinesis was more evident when the examiner lifted the patient’s lids, thus preventing lid synkinesis during downgaze. Attempted upward saccades did not produce any horizontal gaze deviation. Finally, the patient showed normal Bell’s phenomenon. An EEG showed frontal, bilateral theta and theta/delta activity and sporadic drowsiness, and MRI (figure) disclosed a bilateral thalamomesencephalic infarct which involved predominantly the right side.

Horizontal gaze deviation on attempted downward saccades disappeared after about 15 days, whereas vertical gaze impairment and hypersomnia were unchanged 1 year later. Subsequent polysomnographic testing disclosed sleep apnoea.

The clinical features of our patient are those reported for thalamic infarct involving the rostrointerstitial nucleus of the medial longitudinal fasciculus (riMLF). By contrast, the leftward gaze deviation elicited by the attempt to make a downward saccade is at variance with all previous descriptions.

The triggering of a saccade requires not only the activation of the exotatory burst neurons (EBNs), but also the deactivation of the omnipause neurons (OPNs), which provide tonic inhibition of both horizontal and vertical EBNs.

Accordingly, any attempt to activate a lesioned riMLF should be associated with maximal OPN inhibition. However, OPNs discharge for saccade in any direction and are not strictly direction selective, as shown by horizontal oscillations during vertical saccades detectable in normal subjects. These oscillations suggest that during vertical saccades the inhibition of OPNs disinhibits both vertical and, to a lesser extent, horizontal EBNs.

In our patient, the horizontal gaze deviation was always directed to the left rather than in both directions as during oscillations. Many ocular motor structures, including those located in the midbrain, trigger a purely vertical (downward) saccade only when stimulated bilaterally, so as to nullify horizontal components with different direction depending on the stimulation side. This probably occurs for the riMLF too, as it shows ipsilateral projections to the abducens nucleus. In our patient, the projections to the left nucleus were probably spared by the fact that the lesion predominantly affected the right side.

Overall, our patient’s horizontal ocular motor synkinesis is unusual, and probably derives from a strong inhibition of OPNs, which in turn frees the horizontal EBNs, and from an unbalanced activation of the left abducens neurons via riMLF projections spared from the lesion, although it is not possible to exclude the possibility that the unbalanced activation of abducens neurons originated from frontal or parietal cortical areas or from the superior colliculus rather than from riMLF projections.

This hypothesis is strengthened by the reinforcement of the leftward eye deviation when the examiner kept the patient’s lids lifted. Since this manoeuvre prevents lid synkinesis, it results in what resembles an attempted forced lid closure which, on the basis of blink induced eye oscillations, is likely to be an additional stimulus for OPN inhibition. Moreover, although they occur in various conditions, saccade oscillations during fixation are in keeping with a reduction of OPN inhibition level.

In conclusion, our patient presented an ocular motor synkinesis that should be listed among those occurring in thalamomesencephalic infarcts. This sign is unusual and it is likely to be overlooked, but it is fully explicable both by neurophysiology and

\[ \text{(A) and (B) show a thalamomesencephalic sicaemic lesion, hyperintense in T2 weighted scans (SE, TR=2300 ms; TE=25 ms). The lesion involves the anteromedial portion of both thalami, but the right one to a larger extent. In the midbrain, the lesion is located around the Sylvian aqueduct, and symmetrically, but prevalently right sided, and involves the area that is located posteroomedially with respect to both red nuclei.} \]

\[ \text{(C) Recording of the horizontal (upper tracing) and of the vertical (bottom tracing) movements recorded respectively from the left and right eye with the infrared reflection technique (Skalar, IRIS system) during an attempted downward saccade. The vertical tracing is flat, as the patient was unable to move his eyes downward. By contrast, the horizontal tracing shows a concomitant leftward saccade. At outset, both tracings show a blink artifact.} \]
by anatomical connections of the saccade system.

Botulinum toxin is a useful treatment in excessive drooling of saliva

Excessive drooling of saliva or hypersialorrhea is a common problem in neurodegenerative disorders such as motor neuron disease or Parkinson’s disease. It is usually caused by swallowing dysfunction and can facilitate choking, aspiration, and chest infections. Socially it is embarrassing and disabling.

There are not many treatment options. Anticholinergic drugs are sometimes tried but are usually of little benefit and side effects (orthostatic hypotension, dizziness, and mental confusion, particularly in the elderly) limit their usefulness.

Occasionally, as a more drastic treatment irradiation of the parotid gland is carried out when hypersialorrhea becomes intractable.

Apart from its established usefulness in dystonia, the use of botulinum toxin in cranial and striatocerebral dystonias is now also considered. One such case is that of a patient with young-onset dystonic oculogyric crisis who was treated with botulinum toxin for the oculogyric component of the dystonia. The patient showed a marked improvement in both the oculogyric crisis and the overall dystonic symptoms, with a reduction in the need for concomitant anticholinergic medication.

Botulinum toxin inhibits acetylcholine release in nerve terminals mainly at the neuro-muscular junction, but also in sympathetic and parasympathetic ganglion cells and in postganglionic parasympathetic nerves, by blocking SNAP-25, a protein involved in the fusion of acetylcholine containing vesicles with the plasma membrane.1

Against this background we evaluated the usefulness of botulinum toxin injections into the parotid gland in four patients with excessive drooling of saliva in their consent. One patient had young onset secondary generalized dystonia with severe mouth opening spasms, one had advanced Parkinson’s disease, the third patient had progressive supranuclear palsy, and the fourth patient had motor neuron disease. Drooling in these patients was so severe that they had to wear a bib or carry a towel around their neck. With one exception 20 units of Dysport® ( Ipsen) were injected superficially subcutaneously above the angle of the mandible at the posterior margin of the masseter muscle, avoiding the bulk of the muscle. The short version (5/6) of the 25 gauge needle was used. Because worsening of dysphagia was feared only 10 U Dysport were injected into each parotid gland in the patient with motor neuron disease. Drooling did not significantly improve in the first months after the injection due to the low dose of botulinum toxin used. He declined further treatment.

All the other patients had a beneficial response beginning by the end of the first week and lasting 6 weeks in one patient and 3 to 4 months in the others. Apart from subjective improvement reported by the patients and caregivers, reduction of drooling was demonstrated by the fact that the patients did not have to use a bib or towel. One patient had mild worsening of existing dysphagia. Two patients had mild chewing difficulties possibly due to diffusion of the toxin into the masseter and only one complained of a dry mouth. None developed facial weakness. All three patients considered the response good enough and side effects sufficiently minimal for them to continue botulinum toxin treatment at regular intervals.

Injections of botulinum toxin into the parotid gland (and other salivary glands) may be an effective and simple treatment for excessive disabling drooling of saliva in selected patients.

Systemic sclerosis (scleroderma) is a multi-system connective tissue disease of unknown aetiology, characterised by progressive fibrosis of the skin and internal organs including the lungs and gastrointestinal tract.1 Pathological localisation of soft tissues (known as calcinosis) is a common feature in the CREST syndrome of scleroderma (calcinosis, Raynaud’s phenomenon, oesophageal dysmotility, sclerodactyly, and telangiectasias). By contrast, internal organ calcification is rare, and isolated cases of spinal calcification and calcific constrictive pericarditis have been reported.2 We report here the cases of two patients with systemic sclerosis whose CT examination disclosed extensive brain calcifications.

Case 1, a 48 year old man was referred to hospital because of polyarthralgia involving the wrists and ankles, Raynaud’s phenomenon, and keratoconjunctivitis sicca. His father had these features at a later age. The patient’s wife had noticed that during the previous months, he had a slowed mentation and a depressive mood. Physical examination disclosed a scleroderma hand deformity and telangiectasias. Routine haematological tests were normal. Antinuclear antibodies were positive at a 1:2000 dilution with nuclear fluorescence. Rheumatoid factors, antinuclear, strab DNA, and antithrombin III were all negative. There was no cryoglobulinaemia.

Complement was normal. Lung function tests showed a restrictive syndrome (forced vital capacity 75% predicted). Chest radiography was normal, as were oesophageal manometry and cardiac ultrasonographic examination. A diagnosis of systemic sclerosis was made and the patient was given diltiazem (180 mg/day) and ketoprofene (150 mg/day). Six months later the disease activity score had worsened. He complained of memory loss, poor concentration, and insomnia. On neurological examination he was anxious and very slow in answering questions. Mini mental state examination score was 22/30. The patient was oriented to place, but not to time. Anterograde amnesia was noted. Agnosia, apraxia, and aphasis were absent. There was no muscle weakness and muscle tone was normal, as were deep tendon reflexes. Plantar responses were both flexor. There was no sensory loss or impairment of cranial nerves. Systemic sclerosis signs were unchanged. Routine hematological tests were normal. Results of blood chemical tests were also unremarkable (serum electrolytes, urea, creatinine, iron), including phosphorus and calcium metabolism (serum parathyroid hormone concentration, blood calcium and phosphorus, 25-hydroxyvitamin D, 1,25 dihydroxyvitamin D, calcitriol, and phosphatidyl). Serum concentrations of free triothyroxine, free thyroxine, and thyroid stimulating hormone were normal. Serological tests for syphilis, HIV-1,2, and Lyme disease were negative. Brain CT showed bilateral extensive calcification in the dentate nuclei (figure 1A), basal ganglia, and subcortical white matter (figure 1B). On MRI T1 weighted images and T2 weighted images, calcification was visible as a low intensity signal. The patient was given fluoxetine (20 mg/day) and bromazepam (6 mg/day). At follow up, 1 year later, the patient’s clinical status was unchanged, as was brain CT.

Case 2, a 64 year old right handed woman was admitted to hospital for evaluation of a Raynaud’s phenomenon which had lasted for more than 10 years. At physical examination, sclerodactyly and tightness of the facial skin

Letters, Correspondence, Book reviews, Correction
Calcification of the brain is discovered in 0.8 to 1.2% of subjects undergoing routine CT examination, mainly in the globus pallidus. In most cases the deposits are small and involve older patients who remain asymptomatic... leading to the concept of physiological senescent basal ganglia calcifications. On the other hand, basal ganglia calcifications, often associated with dentate nuclei calcifications, have been reported in more than 30 conditions, including abnormalities of calcium phosphorus metabolism such as pseudohypoparathyroidism. Systemic sclerosis leads to the formation of calcium deposits in the subcutaneous tissue. Rarely, the calcific process has been shown to involve the spine or pericardium. Recently, Heron et al described two cases of cerebral involvement in systemic sclerosis. In both cases necropsy showed extensive wall calcification of the small arteries and arterioles of the brain. Our two patients have scleroderma and extensive striopallidodentate calcifications and metabolic investigations failed to disclose any specific aetiology in either case. We think that scleroderma should be added to the list of conditions described as occurring with basal ganglia calcification. The pathogenesis of the formation of calcium deposits in systemic diseases remains poorly understood. However, pathological calcification can be subdivided into metastatic (occurring in undamaged tissues when extracellular calcium and phosphate concentrations are increased) and dystrophic (occurring in injured tissue when extracellular calcium and phosphate concentrations are normal) calcification. In our patients, as in the patients of Heron et al, the brain calcifying process may be related to primary cerebrovascular changes induced by systemic sclerosis.

Routine brain CT examination in systemic sclerosis could help to determine the true incidence of basal ganglia calcifications and their clinical relevance.

**Brain CT of case 1 shows dense symmetric calcifications in the dentate nuclei (1A) and basal ganglia (1B).**

**CORRESPONDENCE**

All tibial foot: an electrophysiological artifact

Yamashita et al claim they have proved an “all tibial foot” for the motor innervation, an anomalous dual innervation of the tibials anterior muscle by the deep peroneal and posterior tibial nerve, and a sensorial innervation of the skin between the first and second toes by the tibial and deep peroneal nerve in a patient. To support their view they quote the letters of Linden and Berlit and of Glocker et al, ignoring our letter and that of Magistris and Truffer, both considering the conclusions of Linden and Berlit and Glocker et al to be wrong. I point out that the mentioned letter of Linden and Berlit and our response to it were published in the same issue.

We have recorded a compound muscle action potential (CMAP) with a negative initial deflection on tibial nerve stimulation in 83% of 50 subjects, using a surface electrode over the extensor digitorum brevis. In the same subjects no potential was recorded by means of a concentric needle electrode inserted in the extensor digitorum brevis. In our view, this proves that the CMAP recorded by surface electrode over the extensor digitorum brevis on tibial nerve stimulation is a remote potential originated in the plantar muscles (volume conducted potential). Furthermore, we consider that the CMAP recorded over the tibialis anterior muscle by surface electrode on tibial nerve stimulation in the popliteal fossa, as reported by Yamashita et al, represents a volume conduction potential originating in the foot and toe flexors. The sensory nerve action potential recorded dorsally in the space between the first and the second toes on tibial nerve stimulation could also be a volume conducted potential originating in the first common planlar digital nerve, as the distance between this nerve and the recording electrode is short. Such volume conduction phenomena are known to occur on surface recordings from the median nerve at the wrist in severe carpal tunnel syndrome, when the fourth finger is stimulated. It is unclear why Yamashita et al could not record a CMAP over the extensor digitorum brevis bilaterally on deep peroneal nerve stimulation in their young patient who did not have neuropathy. A probable explanation is a bilateral aplasia of the extensor digitorum brevis, comparable with the known aplasia of the thenar. The
appropriate examination would have been a needle EMG of the extensor digitorum brevis.

BOOK REVIEWS

If it moves - measure it. Such is the trend in psychiatry and this has led to a proliferation of assessment scales of variable utility; from the esoteric to the ubiquitous. This book has three strengths: it is, quite genuinely, one of the most useful volumes I have seen for a very long time. It covers everything from the AMTS through the MMSE to the KEG cognitive test. Each scale is presented in full together with a short commentary, critical references and, usefully, an estimated time taken to perform the test together with an address to contact the original author.

The chapters are divided into those covering depression, neuropsychiatric assessments, activities of daily living, global assessments, visible assessments, delirium, caregiver assessments and scales for memory function. This organisation, together with a useful and functional index, will make the task of selecting an appropriate scale much easier in the future. Some of these scales are covered by patent law and my only quibble is that it would have been useful to know which instruments can be reproduced and for what purpose without fear of being billed for the privilege. Maybe highlighting such information would give unpated authors a stimulus to publish in their journal and therefore increase this deplorable practice.

This aside, I cannot recommend this book highly enough. By contrast with books that come highly recommended in diverse reviews but remain pristine on your library shelf, if you are ever fortunate enough to get hold of this volume from your institution library then you will, I guarantee, find it well thumbed. For academics, the book is a prayer answered and will become an essential resource to the planning and execution of any clinical research. For clinicians, psychologists, occupational therapists, and other members of the multidisciplinary old age psychiatry team, the collection of so many scales covering all aspects of mental health of elderly people should encourage the use of valid and reliable assessment tools to enhance rather than detract from good clinical practice. My only question is "Why didn't somebody do this before".

SIMON LOVESTONE

Professor Franco Postacchini is an orthopaedic surgeon at the University "La Sapienza" in Rome and is a well known widely respected spinal surgeon. He is to be congratulated on the production of this book which is wide ranging, comprehensive, and beautifully illustrated. The management of lumbar disc disease is fraught with uncertainty and there are many diagnostic and therapeutic pitfalls. The author has succeeded in addressing most of these controversies in a clear and logical fashion. He occasionally blurs the distinction between theories and established scientific facts forgetting that the practice of medicine and in particular the management of spinal disorders is full of paradoxes. For example, he states that large extruded disc fragments are unlikely to resolve spontaneously and usually require surgical treatment. This seems a logical proposition but my experience is that many of these large extrusions undergo complete clinical and radiological resolution within 2 or 3 months. Paradoxically, it is often the smaller contained disc prolapses which fail to improve with conservative measures. Like many orthopaedic surgeons he is persuaded by the alluring theories of discogenic low back pain and works at the altar of segmental microinstability. However, I agree with much that he has written and differences of emphasis are inevitable in a field that is strong on dogma and short of established truths.

I would have no hesitation in recommending the text to trainees as the book is very readable and makes a good introduction to the management of lumbar disc disease. Nearly all aspects of diagnosis and treatment are covered but I was disappointed with the chapter discussing results of surgery. There is no mention of the use of objective validated disability and quality of life instruments in the assessment of outcome. For a text that aims to be comprehensive this constitutes a serious omission. It is because practitioners have failed to use objective outcome measures to establish the natural history of lumbar disc disease and the effects of therapeutic interventions that there remains so much uncertainty about management. These uncertainties cover (among others) physiotherapy, manipulation, timing of radiology, timing of surgery, whether spinal fusion is ever indicated, and what treatments are clinically and cost effective. Despite these drawbacks, surgeons who manage lumbar disc disorders will want to have a copy of this book, either on their own or their departmental library's shelf.

RODNEY LAING

My first sensation is that such a book is long overdue. There is a paucity of books written by clinicians on this subject compared with the many gloom and doom tracts written by sufferers who have apparently been ill with CFS/PVS/ME for 20 years and which depress the hell out of the patients that I see. Why this lack? Undoubtedly because relatively few doctors want to put their heads above the parapet and profess to a great expertise or desire to see patients with it. It is a condition for which there is no objective test, no objective monitoring of progress, whose symptoms are so vague that they repeatedly defy classification and can only be catalogued. Among those patients with a genuine postinfectious fatigue (who mainly get better relatively quickly) usually is a large group of those with hospital records measured by the kilogram who arrive with shelves of self compiled additional notes and occupy huge periods in the clinic to little effect other than frustration for both doctor and patient. Why they do this is a different story.

So what about the book? Firstly I must say it comes armoured plated against criticism with a pack of glowing references from ennobled and famous physicians on the back. Presumably the authors chose these referees whose major feature in common is distinction in fields other than chronic fatigue syndrome.

So, for whatever reason they were chosen the result is also to make this a poisoned chalice to review if one has the temerity to disagree with such a company.

Chronic fatigue and its Syndromes is written by three psychiatrists. That in itself is a little odd as although psychiatric illness is quite common in the chronic fatigue syndrome group, most patients with chronic fatigue syndrome are very reluctant to be seen on first presentation by psychiatrists. One usually has to reassure them that one is not dismissing their symptoms as psychiatric if one does suggest such a referral. What proportion of patients I wonder go to psychiatrists as their first hospital referral? I would guess very few.

The book is very comprehensive. As a source of references on the subject of fatigue it is encyclopaedic. It begins with a nice history of the syndrome. Of a 428 page book much of which is written by sympathetic physiologists into subjects such as viruses and autoimmunity. The result is a collection of comprehensively referenced and uncritically selected facts from the literature, many of which are very useful, such as the collected data on enterovirus and chronic fatigue syndrome. The book is divided into those covering depression, neuropsychiatric assessments, activities of daily living, global assessments, visible assessments, delirium, caregiver assessments and scales for memory function. This organisation, together with a useful and functional index, will make the task of selecting an appropriate scale much easier in the future. Some of these scales are covered by patent law and my only quibble is that it would have been useful to know which instruments can be reproduced and for what purpose without fear of being billed for the privilege. Maybe highlighting such information would give unpated authors a stimulus to publish in their journal and therefore increase this deplorable practice.

This aside, I cannot recommend this book highly enough. By contrast with books that come highly recommended in diverse reviews but remain pristine on your library shelf, if you are ever fortunate enough to get hold of this volume from your institution library then you will, I guarantee, find it well thumbed. For academics, the book is a prayer answered and will become an essential resource to the planning and execution of any clinical research. For clinicians, psychologists, occupational therapists, and other members of the multidisciplinary old age psychiatry team, the collection of so many scales covering all aspects of mental health of elderly people should encourage the use of valid and reliable assessment tools to enhance rather than detract from good clinical practice. My only question is "Why didn't somebody do this before".
disappointing and somewhat introspective that they do not think that subjects such as neurobiology, microbiology, and immunology might justify equally expert contributors.

Is it an easy read? There is no easy way to write on a subject such as this, bedevilled by lack of objective facts and the writers who have chosen a discursive, debating style which when not tightly controlled can slip towards verbosity. Thus, however, is not a standard medical text book and it would be unfair to make direct comparisons.

Is this a useful book? As a source of references, yes. As a guide to clinicians I am less convinced. The two commonest questions purely mentioned: “How long does the illness last?” and “What are my chances of recovery?” Cognitive behavioural therapy is concisely and usefully summarised.

There is a single page on complementary treatment, which again is often an area of considerable interest to patients notwithstanding the lack of controlled evidence for or against it.

On that note it is perhaps appropriate to quote one very intelligent patient with chronic fatigue syndrome I saw who became ill during his PhD. “I’ve done a lot of reading and internet searching about the causes and possible cures of this, before I came to see you” he said “It seems to me that most people are looking for a bit of that which you are not commonly seen after glandular fever and nobody seems to think it odd that after glandular fever you can feel unwell for quite a long time” he continued “If most people get better from this” (and many do) and if you try all sorts of other treatments like homoeopathy, acupuncture, meditation then the one you choose a discursive, debating style which when not tightly controlled can slip towards verbosity. Thus, however, is not a standard medical text book and it would be unfair to make direct comparisons.

Who should read this book? Certainly the migraine researcher should. Though much of it will be familiar to those who have kept up with the literature, it is nevertheless an attractive and readable account of recent research and information. Moreover, the first chapter (by Lars Edvinsson) and the last chapter (by Peter Goadsby) are very pretty syntheses of the field.

Some of the content like the title is achieved at the expense of some pretty terse prose at times, which can make it difficult for the non-expert to follow. It should be noted that, the title notwithstanding, this book deals almost exclusively with the pathophysiology of migraine, and the reader who buys it to get some insight into the mechanisms of tension-type headaches, or other kinds of headache, is going to be disappointed.

New information about how and why migraine happens continues to break on us in a dizzying succession of waves coming from various journals in different disciplines. We need an accessible, understandable, and unitary vehicle to collect, organise, and present this information. Journals, the Internet, and the abstracting services have their place, but for this purpose nothing beats the book. How well does Lars Edvinsson’s Migraine and Headache Pathophysiology meet this need?

This book has several attractive features. Recognising that some of the world’s best science is now being done in the laboratories of industry, it has enlisted as authors several leading researchers from the major pharmaceutical manufacturing companies, in addition to “the usual suspects” from academia. Not only has this introduced some exciting writers to the “review book” audience, but it has provided a particular insight into the science of determining why drugs work, or don’t work, in migraine. This book is up to date, containing many 1998 references. Another strong point of the book it is comprehensiveness; though only 184 pages long, it covers every major aspect of the pathophysiology of migraine. There are chapters on cranial blood vessels, receptor physiology, neurotransmitters, 5-hydroxytryptamine receptor subtypes, cortical spreading, depression, neurogenic inflammation, arteriovenous shunts, cerebral haemodynamics, and animal modelling. This is achieved at the expense of some pretty terse prose at times, which can make it difficult for the non-expert to follow. It should be noted that, the title notwithstanding, this book deals almost exclusively with the pathophysiology of migraine, and the reader who buys it to get some insight into the mechanisms of tension-type headaches, or other kinds of headache, is going to be disappointed.

There is something about the anachronistic binding of the Handbook of Clinical Neurology series that is rather reassuring. Surely if classic phenomenological neurology is to be found anywhere, it will be between these fake leather embossed covers. This volume, the second of three on the neurology of systemic diseases, does not disappoint. Here, in 450 pages of close type and few illustrations, are covered the neurology of orthopaedic, endocrine, gastrointestinal, and metabolic disorders.

Aminoff and Goetz, the volume editors, have assembled an authoritative panel of authors that equitably straddle the Atlantic. There are detailed reviews of familiar territory such as diabetes, orthopaedic trauma, thyroid diseases, and porphyria. Cole’s historical survey of B12 deficiency is particularly fine. In addition there are excellent chapters on more arcane topics for instance the role of pancreatic transplantation and intestinal pseudo-obstruction. Perhaps the movement disorders associated with coeliac disease could have been mentioned and a chapter on the neurology of inflammatory bowel disorders is certainly lacking. But these are trifling complaints against a text that, with its twin volumes, is significantly more comprehensive than any other account of the neurology of systemic diseases. It is hard to imagine a practicing neurologist requiring (or easily affording) a personal copy of all three volumes, but the local medical library should certainly buy them; both neurologists and general physicians will work the better for having them close to hand.

Advances and Technical Standards In Neurosurgery is sponsored by the European Association of Neurosurgical Societies. The intention is to publish reviews of topics in which recent advances have been made, and to invite acknowledged experts to present in depth accounts of established knowledge in various fields of neurosurgery.

The advances under review in this volume are the contribution of the sepal region to memory, the in vivo metabolic investigation of cerebral gliomas with PET, and the use of image guidance in neurosurgery. In the technical standards society, Professors Valavanis and Yasargil discuss the endovascular treatment of arteriovenous malformations, Dr Guglielmi reports on the interventional neuroradiological treatment of intracranial aneurysms, and Dr. Stefasman and colleagues describe the management of benign intracranial hypertension.

This book is aimed primarily at young neurosurgeons, but is an excellent source of reference for those who are already trained. The fact that it is in its 24th volume is a testament to its success in achieving this objective.

It seems that there is a new specialty in North American neurology, hospitalists. The drive to promote managed health care has apparently resulted in hospitals “faced with a dizzying array of neurologic problems”. Most British neurologists have a ward referral practice and will not be impressed by its elevation to the status of a specialty and still less by the agrammatical title Martin Samuels has chosen for it. Which is a shame, because this book deserves a wide readership. One in the Butterworth Heinemann series of Blue Books of Practical Neurology, it is attractively produced and reasonably well illustrated. Its place on your bookshelf is earned by collating the neurological aspects of diverse medical specialties: to name a few, organ transplantation, orthopaedics, oncology, and urology. A quick glance here before a ward referral might well be rewarding. However, the chapters on more conventional neurological topics, such as neuro-ophthalmology, stroke, and seizures are probably briefer than most neurologists would require. So, for those made dizzy by the delirious patient after bypass, the encephalopathic flap patient on ward, or the weak and wasted on intensive care units, this is for you. And remember: you are a hospitalist neurologist.

Alastair Cole, Alastair Cole

This is one of a new type of medical textbook written to meet the needs of an increasingly informed patient population. Aimed very much at those with multiple sclerosis, their families, and caregivers, it is simple and clearly written with jargon and technical terms kept to a minimum but without patronising. Chronic diseases, and especially multiple sclerosis, are not always well managed by the physician. Too many of us think that there is no cure and feel helpless in a busy clinic faced with the patient with a long list of complaints. There are too few specialty multiple sclerosis clinics in which neurologists, pain specialists, urologists, physiotherapists etc liaise.

Patients often feel left in the dark, unaware which of their symptoms can be attributed to their multiple sclerosis and whether it is “worth bothering a busy doctor”. Many can cite bad experiences in their past when they have been fobbed off with well meaning reassurance but without practical help. Dysaesthesia, sexual problems, and urinary incontinence are only a few of the symptoms that can bring misery to the lives of patients and their families and which are poorly addressed by doctors. This book, in a language accessible to most (and with a glossary to explain some unavoidable jargon), explains multiple sclerosis, its symptoms, and what might realistically be obtained in terms of symptom control. All aspects are covered and nothing considered too trivial; constipation or cold feet might be extremely trying for an individual patient and each is considered.

The old idea that it doesn’t help a patient to know too much about his disease (“it will only make him introspective and hypochondriac”) is outdated. Multiple sclerosis can hit anyone and patients now want, and deserve, to be informed. While doctors find it challenging to be faced with a patient equipped with the latest information downloaded from the internet or well informed having read a book such as this, this is a challenge to which we must be ready to rise. This textbook provides the information patients want and fills the gap left by busy doctors. It should be marketed appropriately and we must be ready to respond to the reaction of patients. Perhaps someone with multiple sclerosis should have been invited to write this review.

GILLIAN HALL
