Acute cauda equina syndrome caused by thrombosis of the inferior vena cava

Deep venous thrombosis of the lower limbs is the most common vascular disorder in hospital. Although the clinical features are not specific, the most important symptoms are oedema, local tenderness, and pain. Well known complications of deep venous thrombosis are pulmonary embolism and chronic venous insufficiency. Neurological complications are uncommon after deep venous thrombosis.

We report on a patient who presented with an acute cauda equina syndrome, which turned out to be caused by thrombosis of the inferior vena cava.

A 58 year old previously healthy white man presented at the emergency department of our hospital with acute severe low back pain irradiating to both legs. The pain in the legs was severe and was located from the lower half of the upper legs down to the feet. He also had noted decreased strength as well as sensory disturbances of both legs. Spontaneous micturition was not possible.

On physical examination, blood pressure was 110 over 75 mm Hg. Heart, lungs, and abdomen were normal. Peripheral arterial pulsations were present. Both legs were slightly swollen and coloured red to purple and livido reticularis was present. On catherisation of the bladder, there was no urine retention. Neurological examination showed weakness of both legs with proximal strength Medical Research Council (MRC) grade 2–3 and distal MRC grade 1–2. There was bilateral sensory loss in the dermatomes L1 to S1. Tendon reflexes of the legs were absent. Plantar responses were both indifferent. The patient was diagnosed as having an acute cauda equina syndrome with possibly deep venous thrombosis of both legs, and an immediate MRI of the thoracic and lumbar spine was performed. This MRI disclosed a strongly dilated anterior epidural venous plexus with compression of the cauda equina and nerve roots in the foramina (fig 1 A–C). Signal intensity of the thoracic spinal cord was normal. Ultrasound examination of the lower abdomen and legs showed thrombosis of the inferior caval vein. Abdominal CT confirmed the presence of thrombosis of the inferior caval vein (just below the insertion of the renal veins) extending into the iliac veins. No other abnormalities that could have caused the inferior vena cava thrombosis were seen on CT. Routine laboratory investigations (including coagulability testing) were unremarkable, except for slight increase in erythrocyte sedimentation rate.

The patient was diagnosed as having an acute cauda equina syndrome due to dilated anterior epidural veins secondary to thrombosis of the inferior vena cava. He was treated with intravenous heparin and acenocoumarol to prevent spread of thrombosis. In the next few days, the neurological disturbances gradually diminished. Despite exhaustive testing, no cause of the thrombosis was found.

We report on a patient with an acute cauda equina syndrome due to thrombosis of the inferior vena cava. An acute cauda equina syndrome is usually caused by a prolapsed intervertebral disc and less often by a tumour, trauma, or epidural bleeding. Well known complications of deep venous thrombosis are pulmonary embolism and chronic venous insufficiency. To our knowledge, an acute cauda equina syndrome secondary to thrombosis of the inferior vena cava has not been reported previously.

The mechanism by which the neurological symptoms and signs were produced is probably twofold. Firstly, there is compression of cauda equina nerve roots in the spinal canal and foramen by the dilated anterior internal vertebral veins. Secondly, the symptoms and signs may be due to ischaemia of the cauda equina caused by stasis of the blood flow in the radicular veins. The mentioned anterior internal vertebral veins and radicular veins are part of the spinal venous plexus.

Acute cauda equina syndrome is usually caused by a prolapsed intervertebral disc and less often by a tumour, trauma, or epidural bleeding. Well known complications of deep venous thrombosis are pulmonary embolism and chronic venous insufficiency. To our knowledge, an acute cauda equina syndrome secondary to thrombosis of the inferior vena cava has not been reported previously.

Persisting rhinorrhoea and headache as the initial symptom of bilateral carotid artery dissection

Carotid artery dissection is a frequent non-atherosclerotic cause of stroke in young adults. In up to 20% of cases it is bilateral or associated with vertebral artery dissection.\(^2\)

Common clinical features include unilateral pain on the side of the dissection, signs of cerebral ischaemia, ear bruits, and Horner’s syndrome,\(^3\) which is usually incomplete and sometimes transient.\(^4\) Horner’s syndrome is thought to result from a lesion of the periarterial sympathetic plexus caused by the dissection.\(^5\) Rhinorrhoea and nasal congestion have not yet been reported as symptoms of spontaneous carotid artery dissection but have been seen in patients undergoing cranial base surgery.\(^6\) We here describe a patient with spontaneous bilateral carotid artery dissection in whom rhinorrhoea, nasal congestion, and headache were the first symptoms, which preceded the development of incomplete Horner’s syndrome for several weeks.

A previously healthy 33 year old man was referred for evaluation of headache. He admitted to having had rhinorrhoea and nasal stuffiness for 7 weeks. Treatment with antibiotics and corticosteroids before admission had been unsuccessful. An infectious or allergic cause could not be determined. Four weeks later he developed severe periodical retro-orbital headache lasting for hours, and pulsatile tinnitus on the right side. Two weeks before admission he noted severe stabbing retro-orbital pain on the left side irradiating to the neck. This did not respond to aspirin. Pain attacks and vomiting occurred regularly during the afternoon, progressing during the night without fluctuations. Intake of alcohol and nicotine triggered the attacks. He had no history of cluster headache or migraine.

On examination he showed rhinorrhoea, increased lacrimation of the left eye without redness, left eyelid swelling, incomplete Horner’s syndrome on the left side, and ear bruits on the right side that were not detected by auscultation of the skull. There were no other focal neurological deficits, in particular no anhydrosis. Routine laboratory blood tests, screening for cardiovascular diseases, and Doppler sonography were all normal. Cranial magnetic resonance angiography and cerebral digital subtraction angiography showed bilateral dissection of the internal carotid artery with dissecting aneurysms on both sides (figure A-D).

**Anticoagulation with heparin and then dicumarol** was initiated and the patient’s symptoms gradually improved. On follow up examination 6 months and 14 months later, he showed marginal ptosis and a slightly smaller pupil (2 mm) in the dark on the left side, but no headaches, rhinorrhoea, or tinnitus. Cerebral magnetic resonance angiography of the left internal carotid artery was now normal but the dissecting aneurysm of the right internal carotid artery was unchanged. Therefore anticoagulation was continued.

We suggest that in our patient bilateral carotid artery dissection led to a lesion and dysfunction of the sympathetic pericarotid plexus leading to a parasympathomimetic state with nasal hypersecretion and congestion of nasal vessels. This condition was reversible after recanalisation of the left internal carotid artery. Nasal stuffiness or rhinorrhoea may be rarely reported by patients because this phenomenon may be associated only with sympathetic pericarotid lesions after infrequent bilateral internal carotid artery dissections whereas unilateral dissections may cause only a mild and clinically often inapparent irritation.\(^6\)

Cusimano and Sekhar described a syndrome they termed “pseudocerebrospinal fluid rhinorrhoea” with ipsilateral nasal hypersecretion and nasal stuffiness after surgery of the cranial base.\(^7\) In these patients, the pericarotid sympathetic plexus, the petrous or cavernous carotid artery parts, and the greater petrosal nerve had been resected or dissected. Experimental selective parasympathetic nerve activation in the nasal mucosa of the cat leads to an increase in nasal secretion and vascular congestion.\(^8\) Lung found nasal congestion to be related to a withdrawal of sympathetic discharge rather than to an overactivity of the parasympathetic nerves.\(^9\) Thus the nasal hypersecretion and stuffiness in our patient is in agreement with the assumption of a lesion of pericarotid sympathetic nerve fibres after carotid artery dissection.

In the differential diagnosis, cluster headache and paroxysmal hemicrania have to be considered. Our patient’s symptoms differed from typical cluster headache and paroxysmal hemicrania in that headache followed the beginning of autonomous symptoms after...
suffer from pain.

We conclude that structural lesions of sympathetic nerve fibres should be considered when (1) the headache profile is not typical for cluster headache and paroxysmal hemicrania, and (2) autonomous symptoms precede and outlast headache.

White muscle disease in humans: myopathy caused by selenium deficiency in anorexia nervosa under long term total parenteral nutrition

Selenium is an essential trace element that is known to be a component of glutathione peroxidase, a scavenger of hydroperoxides. Its deficiency causes a decrease in glutathione peroxidase function, thereby resulting in oxidative damage to many organs. The two major clinical signs in patients with selenium deficiency are skeletal myopathy and cardiomypathy. White muscle disease, named because of its characteristic acoloration of the muscle is a myopathy caused by selenium deficiency in animals and in the areas where the soil is low in selenium. In humans, it was demonstrated that Keshan disease, dilated cardiomyopathy in the Keshan area in China, was caused by selenium deficiency. In addition, there are reports that selenium deficiency occurs in patients who are nourished by total parenteral nutrition alone for a long time because of inflammatory bowel disease or resection of the intestine due to various intestinal diseases. We experienced a case of anorexia nervosa with skeletal myopathy caused by selenium deficiency under long term parenteral nutrition.

A 28 year old woman was admitted to our hospital with a 7 year history of anorexia nervosa receiving parenteral nutrition intermittently. At admission, she complained of general fatigue, but had no muscle weakness or myalgia. On physical examination, she was moderately cachectic weighing 27 kg from 22 kg. On admission, she complained of general fatigue and had no muscle weakness or myalgia. On examination, the admission weight was 27 kg, height 158 cm. Her skin was dry and her nail beds appeared pale. Because her voluntary food intake was not sufficient to maintain an adequate weight, we started parenteral nutrition. A month after initiation of parenteral nutrition, her body weight had increased from 22 kg to 27 kg and her presenting complaint of general fatigue had disappeared. Instead, she had begun to complain of proximal muscle pain and weakness in all four limbs, and soon after, she had difficulty in walking or standing up.

Laboratory studies showed a rapid rise in creatine kinase to 5638 (normal 5–169) IU/l. Other myogenic enzymes such as myoglobin and aldolase were also raised. Serum electrolys were all within the normal range. Serum thyroxin and thyroid stimulating hormone concentrations were normal, but serum triiodothyronine was slightly decreased because of impaired conversion of thyroxin caused by malnutrition. Serum selenium concentration markedly decreased to 13 (normal 107–171) µg/l, and glutathione peroxidase also decreased to 145 (normal 280–450) IU/l. Serum vitamin E decreased to 0.35 (normal 0.75–1.41) mg/dl despite being added to the parenteral nutrition. Because serum vitamin E concentration often parallels the serum selenium concentration, these antioxidants will compensate for each other. The forearm ischaemic exercise test showed a normal response. Chest radiography showed neither congestive changes nor enlargement of the heart. On an echocardiogram, the wall motion of the left cardiac ventricle was normal. Electromyography of proximal limb muscles showed myopathic patterns. Motor

Microscopic (A,B) and electron microscopic (C,D) findings of muscle biopsy from the left biceps of this patient. (A) Haematoxylin and eosin staining. There were many atrophic changes and intratubular vacuoles. bar=10 µm. (B) Routine ATPase reaction. Predominance of the type II fibre as well as many vacuoles in the fibres. bar=10 µm. (C) Subperimysial and intermyofibrillar clefts composed of amorphous matrix material were found in muscle fibres. Myofibrils showed thinning and interruption. bar=4 µm. (D) There were intermyofibrillar clefts, containing numerous small granules and enlarged mitochondria with normal cristae. bar=1 µm.
and sensory nerve conduction velocities were normal.

The biopsied muscle from her left biceps seemed pale. Histological studies showed severe atrophy of all muscle fibres examined, type II fibre predominance, increased extramyofibrillar fluid without fibrosis, and many vacuoles in the myofibrils (figure 4A) (B). The vacuoles were un stained by oil red O, periodic acid Schiff, or acid phosphatase, and were made up of subperimysial and intramyofibrillar clefs consisting of amorphous matrix material seen by electron microscopy. Myofibrillar architecture was destroyed and associated with loss and thinning of myofibrils. Some mitochondria were enlarged in size, but neither abnormal cristae nor inclusions were seen (figure C, D). These clefs and destroyed architecture of myofibrils would be caused by the intramyofibrillar and intramyofibrillar focal oedema that might be induced by unmetabolised hydroperoxides.

Within several days after a simple change from total parenteral nutrition to oral diet alone, without selenium supplementation, her muscle pain gradually improved. The serum creatine kinase concentration gradually decreased and stand up from a chair. The concentration of serum selenium and glutathione peroxidase decreased to normal with oral diet alone.

Selenium is relatively abundant in meat, fish, and cereals, but there is very little in total parenteral nutrition or liquid formula diets. A patient nourished by total parenteral nutrition alone for a long period may risk selenium depletion, so selenium supplementation is recommended. In 1979 Van Rijs et al reported a patient with a perforated small intestine showing skeletal myopathy during mouth long parenteral nutrition.1 Since then, there have been about 20 cases of selenium deficiency during total parenteral nutrition in the literature worldwide, but most cases received total parenteral nutrition because of the surgery for intestinal diseases or inflammatory bowel diseases. As far as we know, there is no report dealing with a patient with anorexia nervosa accompanied by selenium deficiency, although total parenteral nutrition is a popular method to ameliorate the nutritional state in severely emaciated patients with anorexia nervosa. The phenotypic difference for manifestation of either skeletal myopathy or cardiomyopathy is not understood at present. The living environment, the selenium content of the whole body, and the level of other antioxidants such as vitamin E, seem to influence one another.

Sudden death occurs occasionally in patients with anorexia nervosa because of arrhythmia and heart failure. Because selenium deficiency can cause cardiomyopathy and sudden death, we should carefully monitor for selenium deficiency in anorexia nervosa, especially in patients on long term total parenteral nutrition.

Selective mutism, speech delay, dysmorphisms, and deletion of the short arm of chromosome 18: a distinct entity?

Epileptic (or selective) mutism is a rare psychiatric disorder. Diagnostic criteria in both ICD-10 and DSM-IV include: (a) consistent failure to speak in specific social situations in which there is an expectation for speaking (for example, at school) despite speaking in other situations (for example, at home); (b) the disturbance interferes with educational or occupational achievement or with social communication; (c) it is not better accounted for by a communication disorder or by a lack of knowledge of the spoken language required in the social situation; (d) it has a duration of at least 1 month.1

It typically starts at preschool age, is more common in girls, and is seen in all social strata with shyness, withdrawal, sensitivity or resistance, and internalising behaviour problems as the most common personality features.

We followed up a 7.5 year old girl who was the third child from non-consanguineous parents. She was born normally at 37 weeks of an uneventful pregnancy, with a birth weight of 3.5 kg, length 47 cm, and head circumference 34.5 cm. The American pediatric assessment record was 9 at 5 minutes. Family history was non-contributory. There was neither familial history of psychiatric illness nor of language abnormalities.

Developmental milestones were normal; she acquired her first words at 3 months, sat at 7 months, and walked at 13 months. On the other hand, she presented speech delay as she used single words meaningfully as late as 5 years old and was able to pronounce her first phrases at 3 years. Behavioural anomalies were first registered by her parents between 3 and 4 years, when they noted a reluctance to speak in front of other people. By the age of 4, she used to speak regularly only to one her friends, and she did not talk to nursery staff or to other children. At home, she normally spoke to her parents and her sister but would not speak to them in front of other people.

She first came under our care at the age of 6 years. Physical examination showed a pattern of facial dysmorphisms involving flattened nasal bridge, broad philtrum, wide mouth, megacrania, and micrognathia. Short and broad fingers were also noted. Muscular tone and deep tendon reflexes were normal. No abnormal pyramidal, extrapyramidal, or cerebellar signs were present. She had no dyspraxia. Her height was below the 10th percentile, weight on the 15th percentile, and head circumference on the 10th percentile.

The autism diagnostic interview,2 administered by her mother, showed a score of 9 in the area of communication (cut off level of 8), but she scored 6 in the areas of qualitative impairments in reciprocal social interaction (cut off of 10), and 0 in repetitive behaviours and stereotyped patterns (cut off of 3). Social and imitative play seemed inadequate, but no language abnormalities, reflex abnormalities, phases, neologisms, or pronominal reversal were present. Her social interactions were reciprocal although she usually only smiled at her parents, did not have easy peer relationships, and directed no language towards the hospital staff. However, she was able to engage in good eye contact. Clumsy attempts to interact with other children where made by the patient when she was not directly observed by medical staff.

The patient was also evaluated by the Wechsler intelligence scale for children which showed a performance IQ of 79, and verbal IQ of 70.

Biochemical tests for aminoacidopathies, mucopolysaccharidoses, and lysosomal disorders were normal, as was selective screening for organic acidemias. An isoelectric focusing test for sialotransferrine was normal. Molecular tests for fragile X element were negative. Brain MRI examination, EEG recording, and audiometric tests were normal.

Karyotype analysis of blood cells showed an abnormal chromosomal pattern with deletion of the short arm of chromosome 18, 46XX, del(18), p(11.1) in all metaphases examined. Karyotype analysis was normal in her parents.

Simons et al recently reported the first patient affected by elective mutism associated with deletion of the short arm of chromosome 18, del(18), p(11.1).3 Their patient had developmental abnormalities but these could not account for her social communication disorders, and peculiar dysmorphism were present. We also had the opportunity to study a girl affected by elective mutism in whom karyotype analysis showed an identical deletion of the chromosome 18.

Speech delay, facial dysmorphism such as flattened nasal bridge, broad philtrum, and micrognathia were the main clinical findings. Aulxiological indices were in the low average range; particularly, skull circumference was on the 10th percentile. Her mother told that the microcephaly was present in her family, and short stature appeared when the height of our patient was compared with the midparental height (data not shown). Chromosome analysis testing showed verbal skills and performance in the low range (table). We compared our patient with the one reported by Simons et al (table).4 With the exception of the round face, not seen in our patient, clinical findings of both patients overlapped. Moreover, both patients had speech delay, a similar neuropsychological profile, and the same 18 chromosome abnormality. All these findings allow us to hypothesise that the association of such signs is not by chance and it may be indicative of a distinct clinical entity.

Elective mutism is most probably a heterogeneous syndrome and several aetiological factors such as minimal brain dysfunction, somatic or psychological trauma, particularly during speech development, and a particular family structure especially the mother-child relationship, have been suggested. As a consequence clinical features can be variable and speech delay and dysmorphisms can be found in a subgroup of patients only.5 Moreover, in most patients elective mutism is a transient disorder as it usually appears...

in a few months. By contrast, in our patient as well as in the one reported by Simons et al, elective mutism appears as a chronic disorder and it has been affecting our patient for about 4 years. Therefore, we think that in a subgroup of patients elective mutism is related to a genetic background. This hypothesis is further corroborated by the study of Steinhausen et al, who pointed out that genetic factors play a part in the aetiology of selective mutism, as they found that disorders of speech, language, and psychiatric illness were more common in the relatives of affected than in the control groups.

Deletion of the short arm of chromosome 18 has also been associated with several phenotypic expressions, mental retardation, and autism. However, in our patient diagnosis of elective mutism was firmly made as autism or connected pervasive developmental disorder were ruled out because of social disorders which were highly specific and situational.

In conclusion, we confirm that the relation between elective mutism and deletion of the short arm of the chromosome 18 is not by chance, and think that their association with developmental disorders and dysmorphisms, occurring in these patients, may delineate a specific clinical entity.

Radianov et al reply:

On the basis of our article, which may be interpreted as indicating a relation between brain injury after whiplash, Ferrari focuses on malingering as an alternative explanation for the cognitive problems of whiplash patients. This perhaps is a biased view and is in contrast with Ferrari’s statement that “the biopsychosocial (non-dichotomous) approach to the problem of whiplash” to the problem may be required in these patients. The following points seem important: (1) It should be considered that there were results outside the context of litigation which suggest that overall there was an improvement of cognitive functions (for example, attention) in whiplash patients within the first months of injury. However, there was a relapse in cognitive functioning in long term patients, which could be explained neither by brain damage nor by litigation. Data rather suggested that this relapse may be due to symptoms (mainly pain), adverse effects of medication, or symptoms related to change in psychological functioning. Comparable results were found in additional studies where litigation is unlikely to have played an important role. In this research similar problems in cognitive dysfunction seem to be a particular problem in some countries. In The Netherlands, some 25% of those patients reporting such symptoms months to years after the accident may be malingering. (as detected by testing) was twice as common in litigants than in non-litigants.

Radianov et al are thus contributing to the effort in closing one chapter of the whiplash controversy. Clinicians can now be more confident in relating to their patients that their cognitive dysfunction is due to various reversible factors, rather than brain injury or other ominous diagnoses. Indeed, a re-education of this sort, and the biopsychosocial (non-dichotomous) approach Radianov et al suggest is the cornerstone of more effective approaches towards the prevention of the late whiplash syndrome.
performance were found in patients who had had mild traumatic brain injury or only an injury to other parts of the body. Interestingly, in patients with more severe injuries to other parts of the body a higher impairment in cognitive functioning was found. These results may suggest that experience of symp-
toms (for example, pain) and the process of adjustment to the symptoms (for example, worry about achieving the pretraumatic level of function) may contribute to psycho-
logical changes as shown previously. Based on these changes, of which the prolonged experience of impaired wellbeing may be crucial, an inability for effort may follow, eventually leading to subtle problems in cog-
nitive functioning. Assuming a dichotomous perspective with focus on malinger ing as the only basis for symptoms may certainly lead to an additional change in patients’ illness behaviour including an exaggeration of symptoms in some cases. Considering these issues may help to develop a therapeutic approach which should allow patients to adjust better to their problems and improve recovery. Previous results generally indicate a lack of morphological brain damage after whiplash or mild traumatic brain injury. However, functional brain damage, whatever the cause, cannot be fully excluded and further research may provide some additional insights. For example, using SPECT, short term disturbance to prefrontal structures was found in patients with mild traumatic brain injury, which probably indicated some sort of impaired functioning. Such a functional impairment may introduce a cascade of additional problems eventually contributing to a vicious circle on which basis the previously shown symptom augmentation may follow. This has to be prevented. Blaming patients for malingering is hardly the most appropriate approach and does not have anything to do with a non-
dichotomous perspective of illness behaviour.

Secondary prevention after cerebral ischaemia of presumed arterial origin: is aspirin still the touchstone

I agree that, for secondary prevention of ischaemic stroke, alternatives to aspirin have to be identified, not only because the scope for aspirin related therapeutic benefit is limited by the fact that aspirin blocks only one of at least eight potential pathways for activation of platelet aggregation, but also because some patients, initially responsive to the inhibitory effect of aspirin on platelet aggregation, subsequently escape from this effect, with conse-
quent risk of recurrence of ischaemic stroke. Glycoprotein IIb/IIIa receptor blockers might superficially seem to be the final solution to this problem, as they block the final common pathway of platelet activation, but enthusiasm for their use should be tempered by the acknowledgement that acute profound thrombocytopenia (platelet count< 20 000/mm³) may be an exceptional side effect, with the consequence (at least in theory) of clinically significant intracranial haemorrhage in elderly patients who have ischaemic stroke coexisting with the type of small vessel disease predisposing to silent intracerebral microhaemor-
rhages, or coexisting with cerebral amyloid angiopathy, itself a risk factor for intracranial haemorrhage.

Prospective, population based studies of cavernous malformations are needed

In their welcome systematic review of supratentorial cavernous malformations and epilepsy, Moran et al illustrate the pitfalls of regarding the prognosis of a disease in selected case series as representative of its natural history. Studies of cavernous malformation prognosis have usually lacked clear inception cohorts with respect to mode of presentation and treatment. Recent filter bias has so often restricted ascertainment by tertiary referral centres, and further selection bias has made the prognosis seem worse than it really is, as demonstrated by the authors’ own series of 33 patients in which temporal lobe lesion location and intractable seizures predominated. Conversely, by leaving community mortality unaccounted for, the prognosis can seem better than it actually is. Completeness of follow up has been variable and not always prospective. Furthermore, authors have varied in their choice of period at risk (from birth, time of diagnosis, haemorrhage (clinical or radiological), choice of period at risk (from birth, time of diagnosis, or start of observation) and calculation of outcomes for each patient or for each lesion. Any analyses of such heterogeneous case series are bound to be ruthlessly systematic, but even so it is necessary to be wary about drawing firm conclusions from them.  

The only existing population based study of cavernous malformations, albeit with a denominator of merely 50 000, was retrospective. The study spanned fundamental developments in the non-invasive diagnosis of cavernous malformations during the 1980s with magnetic resonance imaging, which led to increasing detection rates with time. There is, therefore, clearly a need for a large, population based, prospective, contemporary epidemiological survey of cavernous malformations to establish their frequency and prognosis. With a broad collaborative network, including the three other neurosciences centres in Scotland, the Scottish Intracranial Vascular Malformation Study (SIVMS) (www.dcn.ed.ac.uk/ivm/) to do just this for all types of intracranial vascular malformation (IVM). Using multiple, overlapping sources of case ascertainment we are building an invaluable database of all incident cases of any type of IVM diagnosed after 1 January 1999 in the population of Scotland (5.1 million). With prolonged follow up of this cohort we hope to settle some of the uncertainties highlighted by Moran et al. Moreover we agree that, with such poor data available, a randomised controlled trial of surgical versus conservative treatment for cavernous malformations is overdue.

7 Politzer A. Geschichte der Ohrenheilkunde. Stuttgart: Enke, 1907 Band I, 1913 Band II.

Neurological stamp: Adam Politzer (1835–1920)

Recent is an interesting manuscript in your journal about Adam Politzer under the section on neurological stamps. I was mildly disappointed by the presence of some inaccuracies concerning the biography of Adam Politzer, and write to you to correct these impressions. Adam Politzer published in 1878 the first volume of his textbook of otology under the original German title Lehrbuch der Ohrenheilkunde für praktische Ärzte und Studierende. The second edition was published in 1882 to complete his work.1 Since the second edition, this textbook of otology was printed in one volume. The finding that ossicles vibrate to sound stimuli was not made by Politzer but by Hermann von Helmholtz with his resonance theory published in 1863 completed by the mechanism of ossicles and tympanic membrane in 1868.2 Politzer was one of his students in 1861 in Heidelberg. Adam Politzer invented, notably, a revolutionary method to make the eustachian tube permeable in 1863,3 a method which made him famous and carries his name. He also developed an acometor in 1877 to measure hearing, replacing the watch, which was used until this date. In 1864 Politzer founded with Anton von Tröltsch and Hermann Schwartz the first German and international journal of otology under the original title Archiv für Ohrenheilkunde.4 In 1879 The American Journal of Otology4 was founded and edited by Clarence J Blake and was printed for only 4 years at this time. In addition to more than 100 publications in medical journals, and besides his textbook of otology, Politzer published three other books, all translated into English. As well as one book about anatomical and histological dissection of the human ear and one about the history of otology, Politzer published an atlas of the tympanic membrane in 1865,5 completed and reprinted in 1896.6 Politzer was certainly the greatest oto logical of the 19th century and probably one of the greatest of all time. His influence during 50 years of otology has never been equaled.

1 Politzer A. Lehrbuch der Ohrenheilkunde für praktische Ärzte und Studierende. Stuttgart: Enke, 1878 Band I, 1882 Band II.

The authors say that they wrote this book from a fundamental point of view, having to look at different relevant sources to solve a single clinical problem.

The introductory chapters contain sound clinical advice on a general approach to patients with mononeuropathy. Then each nerve is dealt with in turn, often by a different author. The advice on treatment is sensible, the line drawings of power testing are less satisfactory. The move to be tested is well illustrated but the site of the muscle being tested (and hopefully observed) is not shown and for some muscles lies outside the illustration. This is followed by some chapters discussing causes of peripheral nerve injury other than focal lesions, including metabolic and physical factors and tumours. The description of the clinical syndromes is clear and succinct and well referenced throughout. The advice on treatment is sensible with a strong emphasis towards conservative management with clear statements as to when more rapid intervention is needed.

The text is interspersed with illustrative cases which appear in boxes. I thought this worked well, although was surprised to find eight doctorers (including a Professor of Neurology with a personal muscleocutaneous nerve lesion, and a Dean of the Faculty of Medicine with neurogenic amyotrophy), among the 40 or so cases.

For while mononeuropathies the book manages to act as a single point of reference it does not do this for some similar clinical problems whose presentations may be similar. It only briefly touches on radiculopathies as they appear in the differential diagnosis of mononeuropathies and skirts round some contentious issues such as the thoracic outlet syndrome. The anatomy of the brachial plexus (something I always have to look up) is not reproduced.

Overall I think the authors have succeeded in their objectives and there is indeed justification for this book. The book is moderately priced at less than half the price of the combined costs two of the books they aim to replace.

I would suggest that most neurology units should get a copy. I would urge you to persuade your orthopaedic colleagues to get one too.

GN FULLER
This book deals, in general, with issues pertinent to the clinical application of cell transplantation approaches, and has been written by many eminent members of both the American and European transplant communities, the editors also being well respected figures in this field. It covers neuronal cell transplantation therapies in its many forms, and although almost half relates to primary human foetal tissue transplants in Parkinson's and Huntington's disease, this does in fact reflect the balance of evidence and still has a place in issues of transplantation therapy long term on the balance of this condition is probably inherited in autosomal dominant fashion, but only about 10% of siblings have epilepsy and they may have many different clinical varieties of epilepsy. Indeed there seems to be an association between this benign partial epilepsy and idiopathic generalised epilepsy, blurring the classic divisions of epilepsy classification.

Autosomal dominant nocturnal frontal lobe epilepsy is genetically and clinically related to the use of xenogeneic cells, both transplanted directly and also transplanted in their encapsulated form after genetic modification, the latter having already being piloted clinically, particularly for use in chronic pain syndromes. The potential of using cell lines is discussed largely with reference to the use of xenogeneic cells, both transplanted directly and also transplanted in their encapsulated form after genetic modification, the latter having already being piloted clinically, particularly for use in chronic pain syndromes. The potential of using cell lines is mentioned in passing, but stem cell therapies (namely neuronal and embryonic stem cells) are not explicitly discussed, which is perhaps something of a hole given the likely reliance of transplantation therapy long term on the development of alternative sources of donor tissue. The book ends with a single chapter on the ethics of using human foetal tissue. This has been written very much from an American perspective and as this is such a central issue for much of the ongoing work, a more balanced account would have been useful. However, that being said, this is a clear and readable account. It is suitable as an introduction to various aspects of neural cell therapies, and is an essential handbook for anyone working in the field.

ANNE ROSSIER

Are we on the verge of molecular Armageddon, to be ravaged by the onslaught of giant, genetically modified, giant tomatoes? Are we entering a molecular Utopia, where all the world's ills will be solved with a golden key to a nucleotide code or at the gateway of a golden key to a nucleotide code or at the gateway of a paroxysmal disorder, with age dependent expression, no diagnostic test, and frequent misdiagnosis. A tribute to workers in the field is that progress has been made despite these difficulties. Several early chapters consider benign childhood epilepsy with centrotemporal spikes. The characteristic EEG disturbance of this condition is probably inherited in an autosomal dominant fashion, but only about 10% of siblings have epilepsy and they may have many different clinical varieties of epilepsy. Indeed there seems to be an association between this benign partial epilepsy and idiopathic generalised epilepsy, blurring the classic divisions of epilepsy classification.
